When cooling the MMH/H<sub>2</sub>O mixture, glass was readily formed at any cooling rate. The glass transition temperature was in the vicinity of 157 K. Crystallization then occurred during reheating of the sample. Depending on the heating rate, the hydrate crystallized in a metastable form that melted at about 219 K and (or) in a stable form that melted sharply at 234 K. The phase transformation was very slow and may take hours or days. The heat of transformation was measured in an adiabatic calorimeter similar to an accelerating rate calorimeter (ARC). In one example, the crystallization of the metastable phase was complete at 209.3 K and the melting of the metastable phase took place at 222 K. The energy released by the crystallization process increased the temperature of the system from 186 to 222.4 K.

**Figure 23:** Solid–liquid phase diagram for the methylhydrazine/H<sub>2</sub>O system. (Republished and modified from [219], with permission of ©1996 Elsevier, permission conveyed through RightsLink)

Phase transformations in the MMH monohydrate ( $\text{CH}_3\text{NHNH}_2 \cdot \text{H}_2\text{O}$ ) system were investigated using DSC over the temperature range 110–300 K [220, 221]. On cooling of the solution, glass was formed by quenching the liquid. Depending on the heating/cooling rate, two solid phases (metastable and/or stable) with slow-phase transformation kinetics were observed. The optimal temperature for nucleation and growth processes were determined for the two solid phases. The nucleation rate was at a maximum in the glass transition region ( $T_g \cong 160$  K) and the temperature-growth regions were estimated to be 188–202 K for the metastable solid phase and 212–228 K for the stable solid phase. The metastable and the stable solid phases melted at 220 and 234 K, respectively.

The molecular associations of MMH with water were analyzed over a wide range of mixture compositions using Raman and the bond lengths of N—H and O—H were measured as a function of the temperature of the liquid [222]. In addition to the hydrate, there were indications of MMH dimers. Deviations from normal solution behavior were due to hydrogen bonding, also evident from sudden changes of the heat capacity and viscosity of the liquid.

Two monohydrates of MMH were formed by annealing at a low temperature ( $T < 218.9\text{ K}$ ) of supercooled stoichiometric mixtures of MMH and water, and nucleation and crystallization temperature/composition regimes were investigated by DSC [223]. The results agreed with the data deduced from a light scattering method. The formation of each solid phase is controlled by two kinds of nuclei.

Solid-liquid equilibria of the system MMH/water were investigated by direct thermal analysis on heating [224, 225]. Three liquidus curves could be observed corresponding to ice, MMH, and a stable congruently melting MMH monohydrate. Another metastable form of monohydrate could be observed, its transformation into the stable form being monotropic. A model was deduced from the study of the water/alkylhydrazines vapor-liquid equilibria and representing strong interactions between molecules as chemical associations, which allowed one to reproduce all the liquidus curves correctly. This modeling was based on the evolution of Raman spectra of the liquid phase. The crystal structure of pure MMH, determined at 179 K by X-ray diffraction (XRD) on a single crystal, is favorable to the existence of strong interactions between MMH molecules. The model can also be used to reproduce the system UDMH/water.

### 3.2.2 Freezing Points of MMH/Hydrazine Mixtures

Methylhydrazine is a preferred additive to hydrazine to lower its freezing point without changing its specific impulse in bipropellant combinations. Freezing points of MMH/hydrazine mixtures are listed in Table 22 and illustrated in Figure 24. The most important MMH/N<sub>2</sub>H<sub>4</sub> mixture is MHF-3 with 86 mass-% MMH. MHF-3 has a freezing point of 219.26 K (−53.9°C).

### 3.3 Physical Properties of Other MMH Mixtures

In search of a freezing point suppressant for MMH in bipropellant systems, five different organic additives and water were tested to measure freezing points, densities, vapor pressures, and to calculate the potential effect on bipropellant performance with NTO as the oxidizer [226]. The additives tested in quantities between 5 and 40% were: urea, acetamide, 1-methyl-1-phenylhydrazine, *N,N*-dimethylformamide, and formamide. Other than water, which would have lowered performance and caused corrosion, *N,N*-dimethylformamide was the best candidate additive for

**Table 22:** Binary system methylhydrazine–hydrazine freezing point data.

| Composition of mixture, mass-% |           | Freezing point |       |
|--------------------------------|-----------|----------------|-------|
| Methylhydrazine                | Hydrazine | K              | °C    |
| 0.0                            | 100.0     | 274.1          | +1.0  |
| 14.6                           | 85.4      | 270.6          | −2.5  |
| 33.1                           | 66.9      | 264.1          | −9.0  |
| 69.9                           | 30.1      | 244.1          | −29.0 |
| 84.3                           | 15.7      | 224.6          | −48.5 |
| 85.0                           | 15.0      | 222.6          | −50.5 |
| 86.5                           | 13.5      | 217.1          | −56.0 |
| 88.0                           | 12.0      | 213.6          | −59.5 |
| 88.5                           | 11.5      | 214.1          | −59.0 |
| 89.8                           | 10.2      | 214.1          | −59.0 |
| 92.6                           | 7.4       | 217.1          | −56.0 |
| 94.9                           | 5.1       | 219.1          | −54.0 |
| 96.8                           | 3.2       | 218.6          | −54.5 |
| 100.0                          | 0.0       | 220.6          | −52.5 |

lowering the freezing point without excessive loss of performance. Addition of 5% *N,N*-dimethylformamide lowered the freezing point to below 203 K (−70 °C), increased the density at 299 K (26.5 °C) to 0.875 g/cm<sup>3</sup>, and increased the boiling point to 362 K (91 °C). In the system MMH/UDMH, a eutectic freezing at 193 K (−80 °C = −112 °F), appeared at the composition: 39.8 mass-% MMH and 60.2% UDMH [60].

### 3.4 Freezing Points of Ternary MMH Mixtures

Ternary MMH mixtures may occasionally be selected to obtain blends with properties not otherwise achievable with binary mixtures.

#### 3.4.1 Freezing Points of MMH/N<sub>2</sub>H<sub>4</sub>/H<sub>2</sub>O Mixtures

The MMH mixtures listed in Table 23 have been formulated to provide one oxygen for every carbon when these mixtures were used as monopropellants. The addition of water lowers the performance of MMH/N<sub>2</sub>H<sub>4</sub> mixtures as monopropellants and fuels, but it was hoped that the preferential formation of carbon monoxide would avoid the formation of soot in the monopropellant exhaust. At the lower temperatures, the mixtures exhibited extensive supercooling, and only a freezing range rather than a freezing point could be determined [227].

**Table 23:** Freezing ranges of ternary MMH/N<sub>2</sub>H<sub>4</sub>/H<sub>2</sub>O mixtures.

| Composition, mass-% |                               |                  | Freezing range |            |
|---------------------|-------------------------------|------------------|----------------|------------|
| MMH                 | N <sub>2</sub> H <sub>4</sub> | H <sub>2</sub> O | K              | °C         |
| 47.9                | 33.3                          | 18.8             | 223–218        | –50 to –55 |
| 35.9                | 50.0                          | 14.1             | 238–236        | –35 to –33 |
| 25.6                | 64.4                          | 10.0             | 255–250        | –18 to –23 |

Data source: [227]

The freezing (melting) point isotherms of ternary MMH/N<sub>2</sub>H<sub>4</sub>/H<sub>2</sub>O mixtures are illustrated in the triangular chart in Figure 25. Fuel mixtures of interest are marked on the chart as MHF-3, MHF-6, BAF-1014, and BAF-1185.

If one holds the MMH:H<sub>2</sub>O ratio constant at a molar ratio of 1:1 corresponding to MMH hydrate, then the freezing point as a function of added hydrazine is almost a linear function, as illustrated in Figure 26. Note that the abscissa scale is mol-%, not mass-% N<sub>2</sub>H<sub>4</sub>.

#### 3.4.2 Freezing Points of MMH/N<sub>2</sub>H<sub>4</sub>/HN Mixtures

Frequently, the desired low freezing point of hydrazine fuels could not be achieved by adding only one compound. Satisfactory freezing points and performances were achieved only with a number of ternary mixtures that also contained HN as an oxidizer. Mixtures of hydrazine/MMH/HN and also hydrazine/UDMH/HN have been investigated (see Table 24). A mixture with a nominal composition of 23.3% hydrazine, 45.3% MMH, and 31.4% HN freezes at 219.2 K (–65 °F) and has subsequently been named Mixed Hydrazine Fuel-1 (MHF-1). This mixture has been

**Table 24:** Freezing points of MMH/hydrazine/hydrazinium nitrate (HN) mixtures.

| Composition, mass-% |                               |      | Freezing point |       |
|---------------------|-------------------------------|------|----------------|-------|
| MMH                 | N <sub>2</sub> H <sub>4</sub> | HN   | K              | °C    |
| 45.3                | 23.3                          | 31.4 | 219.3          | −53.8 |
| 40.6                | 31.3                          | 28.1 | 228.2          | −44.9 |
| 36.8                | 37.7                          | 25.5 | 237            | −36.1 |
| 31.0                | 47.6                          | 21.4 | 245.4          | −27.7 |

Data source: [227]

thoroughly characterized with regard to physical properties, performance, and material compatibility, but has not found widespread use. All mixtures listed in Table 24 were composed so as to provide sufficient oxygen for all carbon to react to carbon monoxide, thus avoiding carbon deposition when used as a monopropellant.

Freezing (melting) points of the ternary MMH/hydrazine/HN mixtures are illustrated in the triangular graph in Figure 27. The highest performance and lowest freezing point mixture in this graph is MHF-1, but for safety's sake the investigators selecting monopropellants for missile applications backed off and eventually chose MHF-5B for further development.

## 4 Chemical Properties of MMH

### 4.1 Thermal Decomposition of MMH

Thermal decomposition of MMH, similar to that of hydrazine, could occur accidentally or deliberately, as in a rocket engine or gas generator. The conditions leading to accidental decomposition of MMH must be known to prevent accidents.

Throughout the discussion of kinetics and thermodynamics of MMH decomposition it is very important to know the bond dissociation energies, for unless sufficient energy is pumped into the system to break at least one of the bonds, no decomposition would occur, at least not thermodynamically. Molecules are reluctant to dissociate if they have the same bond energy as carbon in diamond, which is a very sturdy material. The activation energy is a barrier to decomposition. In order for MMH to decompose on command, the most frequently used method is the lowering of the activation energy.

The main interest in the slow liquid-phase decomposition of MMH stems from practical concern about unwanted pressure buildup during storage and the effect of various materials it is in contact with on the rate of such buildup. Pressure buildup during storage was and still is an important design consideration. During a 10-year storage test in an all-glass apparatus, the rate of MMH decomposition at 316 K (110 °F) in the absence of metal surfaces and catalytic contaminants was 0.02–0.1%/year [228, 229].

The major products of the thermal decomposition of liquid MMH at 473 K (200 °C) are ammonia, methylamine, azomethane, nitrogen, and methane, plus an unidentified species that has a retention time between those of water and MMH on a Quadrol GC column [206]. Hydrogen was found only in trace amounts and formaldehyde methylhydrazone and hydrogen cyanide (HCN) were not formed in measurable amounts. The stoichiometry based on the analysis of the gaseous products was:

The investigation showed that the decomposition rate of MMH in Pyrex glass is only one-tenth the rate observed with hydrazine. The rate of MMH decomposition in Pyrex at 473 K is 0.017%/h. The presence of a CRES-321 surface increased the decomposition rate of propellant-grade MMH by a factor of 5. Acid catalysis by addition of ammonium chloride accelerated decomposition 100%. BaO-treated  $\text{N}_2\text{H}_4$  was more stable in Pyrex than BaO-treated MMH by a factor of 5. MMH is thus more susceptible to decomposition by acid catalysis than hydrazine itself.

The influence of various substances (including metal salts) in specification-grade and refined-grade MMH was examined to provide an understanding of the factors influencing MMH decomposition [230, 231]. The MMH was purified by drying over  $\text{CaH}_2$  for several days, degassing the sample on a vacuum line, and distilling. The purified MMH contained less than 10 ppm water, ammonia, or methylamine. MMH heated in Pyrex tubes at 448 K (175 °C) yielded the products  $\text{CH}_4$ ,  $\text{N}_2$ ,  $\text{NH}_3$ ,  $\text{CH}_3\text{NH}_2$ , and  $(\text{CH}_3)_2\text{N}_2$ .

Only a trace of  $\text{H}_2$  was formed at temperatures below 403 K (130 °C). The composition of the products could be expressed by the following stoichiometric equation:

where the atoms in the brackets have not been assigned to specific compounds. Propellant-grade MMH (neat, without diluent) decomposed much faster than purified MMH. Although the rate decreased from 0.0095 to 0.0037%/h during the 673-h test at 448 K, the overall decomposition was 2.5%. Under the same conditions, the purified sample had decomposed only 0.8%, and the final rate was 0.0012%/h. Care was taken to exclude  $\text{CO}_2$  from all container tubes. Small amounts (0.003 M) of dissolved nickel and iron increased the decomposition rate of MMH by a factor of 10 at 373 K (100 °C.) Dissolved copper had no appreciable effect. The addition of 1% water to MMH had no effect on its decomposition rate at 448 K (175 °C).

The Aestus engine of the upper stage of ARIANE 5 is fed with MMH under a pressure of 16 bar. The propellant, initially at room temperature, is about 393 K when introduced into the combustion chamber, owing to heating up through the regenerative cooling jacket. As MMH is unstable above 373 K, it was necessary to check its thermal decomposition rate in a steel bomb at up to 500 K [92]. The pressure rise rates as a function of temperature are listed in Table 25. The activation energy derived from the Arrhenius equation was 83.8 kJ/mol.

**Table 25:** Liquid phase decomposition of methylhydrazine in a steel bomb.

| Temperature, K | Pressure rise rate, Pa/s |
|----------------|--------------------------|
| 413.4          | 9.2                      |
| 423.9          | 16.2                     |
| 434.2          | 25.5                     |
| 444.3          | 35.6                     |
| 455.7          | 42                       |
| 465.7          | 82                       |
| 476.2          | 175                      |
| 497.8          | 292                      |

Data source: [92]

#### 4.1.1 Effect of Dissolved Contaminants on the Decomposition of MMH in a Liquid State

The effect of acid-forming materials on the decomposition of MMH is of key importance. The addition of acid-forming materials such as  $\text{NH}_4\text{Cl}$ ,  $\text{HCl}$ ,  $\text{NH}_4\text{NO}_3$ , or  $\text{CO}_2$  have been shown to strongly accelerate the decomposition of hydrazine  $\text{N}_2\text{H}_4$  in the presence of metals [232]. Although similar studies apparently have not been carried out with MMH, the investigation reported in Axworthy [232] found that the addition

of 1%  $\text{NH}_4\text{Cl}$  increased the rate of MMH decomposition at 473 K (200 °C) in Pyrex by a factor of 100 – a more pronounced effect than that observed with hydrazine. The effects of metal surfaces were not investigated. It appears probable, however, that acidic impurities or contaminants are detrimental to the stability of MMH in contact with some metal surfaces.

The unimolecular decomposition of MMH, UDMH, and tetramethylhydrazine vapor was studied at low pressures (0.13 Pa = 0.001 mm Hg) and at 873–1273 K (600–1000 °C), and was found to proceed through the elimination of  $\text{NH}_3$  and  $\text{H}_2$  [233]. The heats for formation of the radicals were  $\cdot\text{NH}_2$  (197 kJ/mol = 47.1 kcal/mol),  $\text{CH}_3\text{N}\cdot\text{H}$  (191 kJ/mol = 45.6 kcal/mol), and  $(\text{CH}_3)_2\text{N}\cdot$  (160 kJ/mol = 38.2 kcal/mol). Both  $(\text{CH}_3)_2\text{NNH}_2$  and  $(\text{CH}_3)_2\text{NN}(\text{CH}_3)_2$  decomposed via N–N scission. At higher pressures, on the order of one atmosphere, and sealed Pyrex tubes at 592 K (319 °C), the decomposition of MMH was more complex, yielding as major products  $\text{CH}_4$ ,  $\text{N}_2$ ,  $\text{NH}_3$ , and  $\text{CH}_3\text{NH}_2$ . In gas-phase experiments at 592 K (319 °C), in which methyl radicals were generated in samples of MMH, no chain reaction was initiated. Instead, a stoichiometric reaction took place shown by these equations:

Methylhydrazine was found to react rapidly with oxygen at a pressure of a few millimeters of mercury and at room temperature. The presence of  $\text{CH}_3\text{N}=\text{NH}$  was confirmed by both IR and MS data, and a suggested reaction sequence is:

and

The condensed phase decomposition reactions of 0.1 M MMH at 592 K (319 °C) in hexadecane showed considerable scatter, which was attributed to the presence of trace amounts of some uncontrollable reaction-promoting material, probably oxygen. The major products were  $\text{CH}_4$ ,  $\text{N}_2$ ,  $\text{NH}_3$ , and  $\text{CH}_3\text{NH}_2$  in the ratio 1:1:0.0:0.5. Hydrogen was a minor product. The rate of decomposition was highly erratic, and apparently some unknown, uncontrollable catalytic factor was operative. The range of rates corresponded to first-order half-lives spanning 6 to 300 h. In other experiments under the same conditions, ullage increases on the order of a factor of three and surface-to-volume increases on the order of a factor of 50 or higher caused minimal changes in both decomposition rate and product nature [234].

Experiments were performed in which soluble metal ions were introduced in solutions with MMH in the ratio MMH : ion = 90 : 1 [230, 235]. The decomposition of MMH in the presence of Fe(III), Fe(II), Cu(II), Ni(II), Zn(II), Mn(II), and Mg(II) is immeasurably

slow at room temperature. At 592 K (319 °C), however, MMH decomposition was total for the first four ions within 3 h. The iron and nickel ions were reduced to the native metals. The introduction of methyl radicals into a sample of MMH at 592 K (319 °C) did not initiate long chain reactions, but rather resulted in a stoichiometric 1:1 decomposition of the material.

Instead of using undiluted MMH and risking runaway decomposition reactions, diluted MMH solutions in hexadecane were used to study the sensitivity of MMH to the presence of transition metal salts [236]. In experiments at 473 K (200 °C) in which the ratio of MMH to metal was 90:1, MMH was completely destroyed within 5 min. when in the presence of Ni(II), Fe(II), or Fe(III). Cu(II), on the other hand, brought about decomposition at a considerably slower rate, only 72% destruction of MMH in 72 h. The product distributions in these experiments were dependent to some extent upon the metal salts present. The degree of MMH decomposition in an experiment with Ni(II) was independent of the presence of oxygen. Thus, there appears to be no synergistic effect operating on MMH destruction when MMH is decomposing in the presence of both O<sub>2</sub> and a transition metal salt.

Methylhydrazine solutions of 0.003 M Ni(II), Fe(II), and Cu(II) (about 200 ppm of metal) were heated to 373 K (100 °C) for periods up to 24 h [230, 237]. The Cu-doped solutions exhibited little if any increased decomposition over a sample without added metal, but the Ni- and Fe-doped solutions decomposed to the extent of 2.6 and 2.2% respectively over that period. The zero-valency metal powders precipitated in each case within 6 h, and although there was no certainty that the ions themselves were catalytic, it was evident that the deposited metals were active catalysts. These results are significant with regard to predicting the long-term storage of MMH fuels, as the metal salts form a sediment that may both foul lines and valves and catalyze MMH decomposition. The presence of both the nitrate and chloride salts of MMH in MMH greatly increased the rate of decomposition.

#### 4.1.2 Effect of Metal Surfaces on Decomposition of Liquid MMH

In an investigation of the compatibility of titanium, CRES-347, Al-2014-T6, A-2024, maraging steel A, and maraging steel B, with MMH at 343 K (70 °C) after 107 days, only the maraging steels gave any indication of instability [238]. The criterion of compatibility was the development of significant pressure in the test capsule compared with the pressure development of controls that contained no metal specimen. The maraging steels had the following compositions: maraging steel A: 18 Ni, 4 Mo, balance Fe; maraging steel B: 20 Ni, 1.5 Ti, balance Fe. In this case, the lack of compatibility may in part be attributed to the presence of molybdenum and high nickel in the alloys. Molybdenum, and possibly nickel, are known to effect decomposition of hydrazine-type fuels. One major product of the slow decomposition for all metals tested was N<sub>2</sub>. No CH<sub>4</sub> was reported and only a trace of H<sub>2</sub> and NH<sub>3</sub> in one test. Methyl amines and formaldehyde methylhydrazone were reported as

decomposition products remaining in the liquid phase. The apparent absence of methane in these studies is surprising in view of its ubiquity in other decomposition reactions reported in the literature. JPL reported on the decomposition of MMH stored in contact with 6Al-4V Ti, CRES-303, and CRES-304L at 316 K (43 °C) [239]. In contact with both Ti-6Al-4V and CRES-303, MMH decomposition amounted to only 0.18% of the propellant weight in 1368 days. A slightly smaller (0.15%) decomposition was noted in contact with CRES-304L for 150 days. Approximately equivalent amounts of N<sub>2</sub> and CH<sub>4</sub> were found in the volatile products of decomposition.

The surfaces of the metal alloys, aluminums 6061, 1100, 2014; stainless steels 347, 321, and 17-7PH; and Inconel X-750, showed little to no effect on the decomposition of neat MMH in runs at 373 K (100 °C) for 7 days [236]. Propellant-grade MMH was stored in contact with various metal surfaces at 373 K (100 °C) for 7 days, and the observed stability order was Al about equal to Ti about equal to Cr < Fe < Mo < Ni [240]. The degrees of decomposition due to the metal surface ranged from essentially zero for Al, Ti, and Cr to about 5% for Ni under these conditions. In an experiment conducted at 423 K (150 °C) for up to 356 h, propellant-grade MMH samples appeared to be as stable as samples of purified material. Thus, the impurities present in propellant-grade MMH seemed to have little effect on thermal stability. In studies carried out at 448 K (175 °C) on purified material in both the vapor and liquid phases and in which the amount of Pyrex surface was varied, the rate of MMH decomposition was found to be roughly first order in surface area and zero order in MMH itself. The surfaces of the metal alloys, aluminums 6061, 1100, 2014; stainless steels 347, 321, and 17-7PH; and Inconel X-750, showed no adverse effect on the decomposition of neat MMH in runs at 373 K (100 °C) for 7 days.

A vapor-phase exothermicity test (VPET) and a liquid-phase exothermicity test (LPET) were used at NASA WSTF to test the compatibility of MMH vapor or liquid with construction materials at an elevated temperature in inert atmospheres [241, 242]. The VPET apparatus itself, a 500-mL Pyrex test chamber, was inert to MMH at 473 K. An amount of 0.02 mL of MMH was squirted on flat-panel test samples in the chamber, and eventual temperature rises were recorded. After the MMH had evaporated and reacted with the sample, the vapor space was purged and the remaining MMH amount analyzed. If the metal sample was incompatible with MMH, as indicated by an exothermic event, only very little undecomposed MMH was remaining. Columbium 300 was one of the materials shown to be incompatible with MMH in these tests. The fuel in the test chamber was consumed in approximately 13 s at 473 K.

The LPET consisted of a smaller, 100-mL stainless-steel chamber. The chamber was made from CRES-304L. The liquid level was adjusted such that 112 cm<sup>2</sup> of the wall was wetted in each test. The bomb was then pressurized with helium or nitrogen to 2760 kPa (400 psig) to prevent the liquid from evaporating. It appears that early tests used helium, but later tests used nitrogen [243]. The system could be operated in the adiabatic (well-insulated) mode or with a heat sink attached to maintain isothermal conditions.

The parameter reported in the LPET test is the exothermic threshold temperature in the presence of the material under test, the initial temperature at which a runaway decomposition is first seen to occur. This temperature gives an indication of the relative catalytic activity/incompatibility and needs to be compared with the temperature at which the empty chamber by itself would cause hydrazine(s) to decompose. The absolute value of the LPET exo temperature is highly system dependent and should not be taken as applicable to all situations. In many cases, a temperature range instead of a specific temperature number was given to emphasize the inaccuracy of the data in Table 26.

Comparing the VPET and LPET energy release rates of MMH, the liquid phase produced more severe exothermic reactions than the vapor phase with any of the ten materials tested. In another early test series with MMH in the LPET, 5 out of 12 materials produced varying degrees of exothermic reactions [242]. In most cases, metallic materials that exhibited exothermicity in the liquid MMH/LPET would also react exothermically with MMH vapor in the VPET.

**Table 26:** Liquid-phase exothermicity test results for materials in contact with methylhydrazine or hydrazine in nitrogen.

| Material                                          | Exothermic threshold temperature, K |                               |                      |
|---------------------------------------------------|-------------------------------------|-------------------------------|----------------------|
|                                                   | N <sub>2</sub> H <sub>4</sub>       | N <sub>2</sub> H <sub>4</sub> | MMH                  |

A comparison of the heating rates and onset of exothermicity of hydrazine, H-70, and MMH in titanium in an ARC showed that with hydrazine the onset was at 468 K, with H-70 it was at 483 K, and with MMH it was at 490 K [244]. The stepwise discontinuity (seen at the point where all liquid hydrazine was consumed) did not appear with H-70. With MMH, the step was seen at 510–513 K. The isokinetic temperatures for the three propellants were 523, 527, and 555 K respectively. Additional tests with MMH in the absence of any added catalysts showed that the thermal decomposition products were dinitrogen, ammonia, methane, methylamine, dimethyldiazene, and traces of ethane, propane, ethylene, acetylene, ethylamine, 1-methyl-2-ethyldiazene, dimethylamine, trimethylamine, UDMH, and SDMH [245]. Hydrogen was only present at less than 0.1%. This list of reaction products shows that the thermal decomposition of MMH is a very complex reaction. It was assumed that dimethyldiazene decomposes to diazomethane  $\text{CH}_2\text{N}_2$ , which is a very active methylating agent and is responsible for methylating some of the N–H and C–H bonds in the reaction mixture, leading to di- and tri-methylamines and polymethylhydrazines along with C–C compounds. It was difficult to determine the activation energy of MMH decomposition in the titanium bulb, as the rates varied substantially from test to test. The stoichiometry of the MMH decomposition can be approximated by the reaction sequence:

where  $X$  is a variable (typically  $X = 0.07$ ) and “ $\text{CH}_3$ ” groups all other organics and treats them as ethane.

The decomposition of MMH in contact with a wide variety of materials of construction was tested in an ARC in a titanium bulb [246]. The materials tested were used in powder form, or, where not available, in the form of fine turnings. In either case, the surface areas were measured first and used to normalize the reaction rates. The results, expressed in the form of relative reactivity of various materials normalized by the reactivity of the empty titanium bulb (activity arbitrarily set to 1.0) and at a common temperature of 353 K are summarized in Table 27, sorted in descending order of reactivity.

**Table 27:** Relative reactivity of materials of construction with methylhydrazine.

Data source: [246]

There appears to be a correlation between metals that actively catalyze the decomposition of hydrazine and those that catalyze the decomposition of MMH. One is often tempted to list only the energy of activation of various reactions, such as the heterogeneous decomposition of MMH, as a measure of incompatibility. However, it is better to list the relative reaction rates, correlated for a common temperature point.

#### 4.1.3 Autodecomposition Temperature of MMH in the Absence of Air

Although only rare nowadays, a method that was at one time widely used method for determining the thermal stability of monopropellants and explosives was the Interagency Chemical Rocket Propulsion Group (later Joint Army Navy NASA Air Force) Liquid Propellant Test Method No. 6 [247]. It used a 2.5-mL bombulet holding a 0.5-mL sample immersed in a molten metal bath (Wood's metal) preheated to 460 K. The bath temperature and the differential temperature between the bath and the propellant sample are recorded in order to detect the onset of exotherms. The results of thermal stability tests with hydrazine, MMH, MHF-5, and MHF-7 are summarized in Table 28.

Only the lowest temperature at which exotherms occurred or burst disks ruptured are listed. (The original source showed a range of temperatures.) There is a distinct dependence of the exotherm and disk rupture temperatures on the material from which the bombulets were made. The heating rate was 5.5 K/min. The stability was best in Inconel-X or CRES-321 and worst in aluminum. With MMH, the stability was best in Hastelloy-X and worst in aluminum. In comparative tests where hydrazine or MMH vapors only were contained in the bombulets the burst disks ruptured at lower temperatures than in the liquid tests. Rupture occurred at temperatures 55 K below those measured in the liquid tests, and MHF-5 was much less stable than any of the other propellants.

Until the 1980s, exothermicity tests had to be conducted in fairly large experimental setups to obtain measurable heat flows. Such large tests could not be conducted in a normal chemistry laboratory and had to be relegated to remotely located hazardous test facilities with concrete walls. This situation changed when first DSCs and then ARCs and microcalorimeters became commercially available. These instruments are now found in most energetic materials laboratories and enable the investigators to conduct rocket propellant exothermicity tests in the comfort of a laboratory. The current section deals mostly with the thermal stability of liquids as they affect their safety and hazard properties. Kinetics of hydrazine decomposition reactions are discussed in Section 4.1.4. More hazardous, uncontrolled decomposition reactions are those occurring in cook-off and bonfire tests. Before elaborately setting up an expensive and potentially catastrophic cook-off test, it would be advisable to totally characterize the propellant using DSC and ARC tests. These tests can be conducted in the laboratory and consume less sample. They are standardized by the American Society for Testing and Materials (ASTM) E-698-79 *Standard Test Method for Arrhenius Kinetic Constants for Thermally Unstable Materials*. With MMH, the onset of exothermicity in

**Table 28:** Interagency Chemical Rocket Propulsion Group thermal stability test results for methylhydrazine (MMH) and mixed hydrazine fuels (MHF) blends (Sorted by fuel and materials name).

| Fuel                          | Material    | Exotherm |     | Disk rupture |                     |

Data source: [247]

a titanium bulb in the ARC in the absence of other metals was at 490 K [244, 245]. Nitrogen, ammonia, methylamine, methane, and ethane were the major decomposition products. Dimethylamine, 1,2-dimethyldiazene, and traces of nine other nitrogenous compounds or hydrocarbons were observed in the decomposition product mixture. The Arrhenius parameters for the decomposition reaction were compensated and linearly related by the relationship:

$$\ln A = \frac{E_a}{R\theta} + \ln k_0$$

with a compensation temperature  $\theta$  of 478 K. The isokinetic temperature was 475 K. Activation energies were found to be within the range 71.8–114.8 kJ/mol.

Prior to the availability of ARC, it was attempted to obtain thermal stability, kinetic rate and activation energy data by testing MMH in a DSC [248]. The difficulty encountered with all testing of liquid samples in a DSC is the pressure buildup first due to evaporation and then to decomposition products, which causes conventional sample holders (crimped metal pans, glass vials, capillaries, sometimes called “crucibles” although they are no longer crucible-shaped) to bulge, leak, and rupture. Puncturing the lid with a pinhole allows some of the pressure to vent, but also results in sample loss. ASTM Methods E557 (DTA) and E698 (Arrhenius kinetics) deal with these problems insufficiently, and little progress has been made for DSC of hydrazine or MMH. The internal pressure in the crucibles can be compensated for by enclosing the sample cell and the reference cell in a pressurized enclosure and/or using pressure-resistant crucibles. The increased thermal mass of heavier walls reduces the sensitivity of the method. The first exotherm of MMH began to appear at 390 K. The addition of gold powder to MMH caused another secondary exotherm at 500 K.

#### 4.1.4 Kinetics of MMH Vapor Decomposition

When comparing the ease of decomposition of hydrazine and methylhydrazines, one seeming contradiction is the fact that the rate constant for UDMH at a given temperature is higher than that of MMH or hydrazine, although in other parts of this book it was stated that the thermal stability of hydrazine increases in the order hydrazine, MMH, and UDMH. Apparently, additional factors become important in the decomposition of hydrazine at higher concentrations than those studied in the Princeton reactor. A comparison of rates of decomposition in the Princeton flow reactor was shown in *Encyclopedia of Liquid Fuels*, chapter “Hydrazine,” Figure 40, which showed the rate constants of thermal decomposition of hydrazine and its methyl derivatives as a function of reciprocal absolute temperature. The activation energy could be derived from the slope of these lines.

The thermal decomposition of MMH has been investigated using the toluene carrier method previously used for hydrazine [249]. The rate constants were calculated from the total amount of MMH decomposed and the amounts of nitrogen and ammo-

nia formed. The rate constant did not change when the surface: volume ratio of the reactor was varied. It remained fairly constant in the range 26–159 Pa (0.2–1.2 mm Hg) reactant pressure, 1.33–4 kPa (10–30 mm Hg) toluene pressure, and contact times in the order of 0.5–1.5 s. The Arrhenius plot for MMH decomposition can be represented by the equation:

$$\log k = 13.19 \frac{51900}{2.3RT} \quad \text{s}^{-1}.$$

The decomposition of MMH in the Princeton adiabatic flow reactor showed that the reaction is of first order, and based on their data the rate constant can be expressed as:

$$k = 10^{13.4} e^{\frac{-47000}{RT}} \quad \text{s}^{-1}.$$

This is very similar to the equation presented by Kerr et al. [249]. The stoichiometry based on gas analysis was represented by the following equation:

It is surprising to note that more hydrogen and considerably more HCN is formed than in the case of UDMH decomposition. The mechanism outlined in Table 29 was proposed for this reaction. This mechanism is more complex than that of hydrazine decomposition but less complex than that for UDMH decomposition. Several assump-

**Table 29:** Mechanism and rate constants of methylhydrazine decomposition.

| Reaction number        | Reaction                                                                                                    | Rate constant                                                                         |

Data source: [198]

tions, such as using heats of reaction in place of activation energies, had to be made in suggesting rate constants listed in Table 29. Insufficient data were available on individual steps of the reaction.

Decomposition of MMH in a quartz chamber heated to up to 1273 K preceding a time-of-flight mass spectrometer showed that significant decomposition occurred only above 800 K [250]. The relative intensity of 12 mass peaks of MMH and MMH decomposition products was plotted over the entire range 273–1273 K, with and without the presence of Shell 405 catalyst in the decomposition chamber. Under these conditions, MMH decomposition proceeded by way of the following equation:

The HCN concentration peaked at 900 K and diminished at higher temperatures because HCN in turn decomposed to the elements in a subsequent reaction:

The maximum HCN abundance was very sharp and HCN decomposition above 900 K was more complete if an iridium catalyst was added to the decomposition chamber. The peak at a mass: charge ratio  $m/e$  of 30 was assigned to methylimine  $\text{CH}_3\text{NH}$  instead of ethane. Although ethane formation by methyl radical recombination has been proposed by Eberstein:

the occurrence of methylimine as an intermediate is more likely:

The rate constants for overall MMH decomposition were determined by very low-pressure pyrolysis (VLPP) [251]. The pyrolysis of a flowing gas in a reactor at a very low pressure where the molecular flow region is attained can be described by the Rice–Ramsperger–Kassel–Marcus theory. The product peaks at  $17m/e$  ( $= \text{NH}_3$ ) and  $2m/e$  ( $= \text{H}_2$ ) were used to compute rate constants for the formation of  $\text{NH}_3$  and  $\text{H}_2$  respectively. When  $\text{NO}_2$  was added as a radical scavenger, the rate of  $\text{H}_2$  and  $\text{NH}_3$  production decreased only insignificantly, suggesting that both were being formed by non-radical pathways. The investigators suggested that under the conditions of their experiment, MMH decomposed to ammonia through a four-center deamination reaction. If the MMH decomposition occurred through N–N homolysis, a higher activation energy would have to be expected. Table 30 gives a summary of calculated versus observed Arrhenius parameters for the VLPP decomposition of MMH and related methylhydrazines.

At 870–1270 K and 0.13 Pa, MMH decomposes through elimination of ammonia and hydrogen. Both MMH and UDMH are believed to decompose by way of N–N scis-

**Table 30:** Arrhenius parameters for pyrolysis of methylhydrazines.

MMH = methylhydrazine; UDMH = unsymmetrical dimethylhydrazine; TMH = tetramethylhydrazine

<sup>a</sup> Refers to a four-center elimination of NH<sub>3</sub> or H<sub>2</sub>

Data source: [251]

sion. At higher pressures (near atmospheric) and temperatures (592K) in sealed Pyrex ampoules, the decomposition mechanism was more complex. Decomposition of MMH is initiated by methyl radicals and leads to methane and nitrogen:

This does not seem to be a chain reaction. MMH vapor at higher pressures or 0.1M MMH solutions in hexadecane solvent decompose under formation of CH<sub>4</sub>, N<sub>2</sub>, NH<sub>3</sub>, and CH<sub>3</sub>NH<sub>2</sub> [230, 234].

The rate constant ( $k_{\text{uni}}$ ) for the first-order disappearance of MMH in a static reactor has been determined under very low-pressure pyrolysis conditions [252]. The  $k_{\text{uni}}$  are not the rate constants of ultimate interest as they reflect the fact that energy transfer competes with the chemical decomposition. Theory allows the determination of the high-pressure rate constants ( $k_a$ ), if the mode of decomposition is known. The heats of formation of the radicals  $\cdot\text{NH}_2$ ,  $\text{CH}_3\text{N}\cdot\text{H}$ , and  $(\text{CH}_3)_2\text{N}\cdot$  are known. These values should be usable for prediction of the activation energy for N—N bond homolysis in the hydrazines. Measured rate constants for UDMH and tetramethylhydrazine bore this out, but the rate constant for MMH did not. This and other evidence led to the conclusion that MMH decomposes via molecular concerted elimination of NH<sub>3</sub> and H<sub>2</sub> and not by N—N bond scission. The activation energy of liquid MMH decomposing in a steel bomb, derived from pressure rise rates as a function of temperature and the Arrhenius equation was 83.8 kJ/mol [92].

If MMH is used in a gas generator for tank pressurization or turbine power, the actual composition of the exhaust gases depends on the operating conditions of the

thermal bed reactor. On the basis of equilibrium calculations, one would expect complete dissociation of ammonia and nearly complete dissociation of methane:

This ideal case would give maximum pressurization efficiency but is never achieved. The worst case would be a reaction that leads to all carbon chemically bound:

Fortunately, this does not happen either. The actual gas composition is somewhere in between. The degree of ammonia and methane dissociation can be expressed by two auxiliary parameters  $X$  and  $Y$ :

In reactor experiments,  $X$  was approximately 0.5 and  $Y$  was approximately 0.33.

Methyldiazene (methyldiimine) is a potential intermediate in the decomposition of MMH. Methyldiazene is the simplest of a number of monoalkyl diazenes that have been prepared [253, 254]. Pure methyldiazene has a melting point of 151 K ( $-122^\circ\text{C}$ ) and boils near 268 K ( $-5^\circ\text{C}$ ). Like diazene itself, the monoalkyl diazenes are more stable than was initially expected. The thermal and photolytic decomposition of methyldiazene in the gas phase leads to methane and nitrogen through a chain reaction propagated by the methyl radical [255]. The question remains whether similar free radical reactions take place during the decomposition of MMH:

If MMH is oxidized or decomposed, methylamino or aminomethyl radicals are expected as intermediates, which may lose another hydrogen atom to form methylene imine. Methylene imine  $\text{H}_2\text{C}=\text{NH}$  is an analog to diazene  $\text{HN}=\text{NH}$ .

One hypothesized mechanism would suggest that SDMH, a compound more carcinogenic than MMH, should also form according to:

#### 4.1.5 Decomposition of MMH in Shock Tubes

The thermal decomposition of MMH vapor was studied by recording MMH absorption at 220 nm of the reacting gas behind a reflected shock wave at temperatures of 900–1370 K, pressures of 140–450 kPa, and in mixtures containing 97.5–99 mol-% argon [256, 257]. Based on previous work [258], a kinetic mechanism was developed over extended temperature and pressure ranges to model these experimental data. Specifically, the temperature and pressure dependence of the unimolecular rate coefficients

on the dissociation of MMH and the associated radicals were calculated by a master equation analysis at temperatures of 300–2000 K and pressures of 1–100 atm based on published thermochemical and kinetic parameters. They were then fitted and incorporated into the kinetic model. This unadjusted model was then used to predict the MMH decomposition profiles at different temperatures and pressures for seven groups of MMH/Ar mixtures and the half-life decomposition times from shock tube experiments. Good agreement was observed below 940 K and above 1150 K for the diluted MMH/Ar mixtures. The model predictions further showed that the overall MMH decomposition rate follows first-order kinetics, and that the N–N bond scission is the most sensitive reaction path for the modeling of the homogeneous decomposition of MMH at elevated pressures. However, the model predictions deviated from the experimental data with the incubation period of approximately 100  $\mu$ s observed in the 1030–1090 K temperature range, and it also predicted longer ignition delays for highly concentrated MMH/Ar mixtures. The discrepancy between the model predictions and experimental data under these special conditions of MMH decomposition was analyzed but is not yet resolved.

Measurements of  $\bullet\text{NH}_2$  and  $\text{NH}_3$  time-histories in MMH pyrolysis with MMH initial concentrations of  $\sim 1\%$  in Ar over the temperature range 941–1252 K at pressures near 202 kPa (2 atm) were performed behind reflected shock waves in a shock tube, using laser absorption techniques and an improved measurement of MMH using IR laser absorption [259].  $\bullet\text{NH}_2$  concentration was measured at the peak of the overlapping doublet lines at  $16739.90\text{ cm}^{-1}$  (597.4 nm).  $\text{NH}_3$  and MMH were measured using direct absorption of  $\text{CO}_2$  laser lines at 9.22 and 10.22  $\mu\text{m}$ . These measurements were then compared with a comprehensive MMH pyrolysis mechanism based on the work of Sun et al. [256] and Zhang et al. [260]. Based on the measurements of  $\bullet\text{NH}_2$  and  $\text{NH}_3$ , it was possible to measure rate coefficients for two key reactions in the MMH pyrolysis system:

These rates combined with the measured overall MMH decomposition rate strongly implied that Reaction (1) is the dominant MMH decomposition channel. The following rate coefficients (202 kPa, 900–1300 K) were determined:

$$\begin{aligned} k_1 &= 1.50 \times 10^{58} \times T^{-12.84} \exp(-39580/T) \text{ s}^{-1} \\ k_2 &= 3.7 \times 10^{14} \exp(-2620/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}. \end{aligned}$$

Based on the MMH measurements, the contribution of the  $\text{CH}_3$  decomposition channel was 0–20% of the  $\text{NH}_2$  channel, and a value of:

$$1.64 \times 10^{58} \times T^{-12.84} \exp(-39580/T) \text{ s}^{-1}.$$

was recommended for the overall unimolecular decomposition of MMH. Further analysis of the  $\text{NH}_2$  measurements indicated that the rate of the following reaction used in the Princeton mechanism should also be significantly increased:

The changes to the MMH pyrolysis mechanism resulted in greatly improved agreement between measured and modeled  $\text{NH}_2$ ,  $\text{NH}_3$ , and MMH time-histories over the entire range of the study.

Pyrolysis of MMH was studied behind reflected shock waves using a laser absorption method [261, 262].  $\text{NH}_2$  concentration time-histories in MMH/argon mixtures were measured over the temperature range 1100–1400 K and pressures of 0.3–5 atm. The MMH pyrolysis mechanism developed by Sun et al. [256], with the update by Cook et al. [259], was used to simulate the  $\text{NH}_2$  time-histories and to compare computations with the experimental results. The rate constant of the reaction  $\text{CH}_3\text{NHNH}_2 \rightarrow \text{CH}_3\text{NH} + \text{NH}_2$  was determined based on the  $\text{NH}_2$  time-history measurements. Pressure dependence of  $k_{1a}$  was observed at 0.3–5 atm. The measured reaction rate constants followed a pressure dependence trend close to the theoretical results by Zhang et al. [260] based on transition state theory master equation analysis, and reducing their theoretical results by a ~40% lead to a close match with the measured data. With the experimentally determined  $k_{1a}$ , the simulation results matched closely with the measured  $\text{NH}_2$  time-histories at early times. Utilizing the later times of the  $\text{NH}_2$  time-histories, a good fit was achieved with the reaction rate constant of:

$$k_2 = 1.5 \times 10^{14} \exp\left(\frac{-755}{T}\right) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

for the reaction  $\text{NHNH}_2 + \text{H} \rightarrow \text{NH}_2 + \text{NH}_2$ . Simulation results using the modified mechanism, with the updated  $k_{1a}$  and  $k_2$ , agreed well with the measured  $\text{NH}_2$  time-histories.

The thermal decomposition of MMH diluted by more than 97% with argon was followed by absorption spectrophotometry at 220 nm within a temperature range between 770 and 1370 K and pressure of between 140 and 455 kPa [263]. This study served as a basis for the validation of a detailed kinetic model with 99 equilibrium reactions and 39 species. Using susceptibility criteria, the mechanism was reduced to 14 reactions and 15 species. Explosive decompositions of MMH diluted between 70 and 80% by argon have been observed. The study of the self-ignition times of  $\text{O}_2/\text{MMH}/\text{Ar}$  mixtures was carried out in a shock tube behind a reflected shock wave. The ignition delay as a function of temperature and initial concentrations and the effect of additives has been studied. It was shown in this study that  $\text{O}_2/\text{MMH}/(\text{diluent})$  mixtures are likely to detonate behind a shock wave. Experimental detonation velocities have been compared with the theoretical Chapman–Jouguet (C-J) velocities. The three-dimensional structure of the detonation waves has been studied using the

soot deposition technique. Criteria of limits of detonability have been proposed by considering the model and the structure of the detonation wave.

Ignition delays have been investigated for mixtures of  $O_2 + MMH + Ar$  at high temperatures (850–1440 K) within the pressure range 160–400 kPa, for equivalence ratios of 1–4.3 and in the Ar dilution range 82–96 mol-% [264]. The replacement of argon by nitrogen led to a twofold increase in the delay. The addition of 0.88–2.4 mol-% hydrogen to the  $O_2 + MMH + Ar$  mixture showed that hydrogen has, globally, a promoting effect on the ignition in  $O_2 + MMH + (Ar)$ . A kinetic model predicted that the addition of MMH should promote hydrogen oxidation within the temperature range 900–1000 K by forming free radicals during its oxidative decomposition.

Gas-phase thermochemical properties of more than 50 compounds expected to play a role in the decomposition and oxidation chemistry of MMH were obtained from high-level *ab initio* quantum chemical calculations [265]. Groups of these compounds were discussed in terms of the conditions under which they were expected to be of potential importance in building a kinetic model of the reaction.

Depending on the amount added, methylhydrazine added in relatively small amounts (up to 10% with respect to hydrogen) can be an inhibitor or a promoter to the reaction of hydrogen and oxygen (diluted with argon) in a shock tube [266, 267]. The efficiency of ignition promotion or inhibition for  $O_2/H_2/Ar$  mixtures was investigated by computations performed with a detailed kinetic model and then validated with experimental ignition delays obtained behind a reflected shock wave in mixtures of  $O_2/MMH/Ar$ ,  $O_2/MMH/H_2/Ar$ , and  $O_2/H_2/Ar$ . Good agreement was obtained between experimental and computed ignition delays with the mixtures of  $O_2/MMH/H_2/Ar$  at high temperatures (900–1170 K) and within the pressure range 225–414 kPa.

Ignition delays of mixtures of  $O_2 + MMH + CH_4 + Ar$  at high temperatures (907–1360 K) within the pressure range 246–412 kPa have been measured in the reflected-shock region of a shock tube [268]. Reaction progress was monitored via piezoelectric pressure transducers and UV absorption by MMH. In the composition range studied, the ignition delays can be correlated by the expression:

$$t(\mu s) = 2.042 \times 10^{-2} [MMH] - 0.87 [O_2] - 2.09 [CH_4] + 0.68 [Ar] 1.24 \exp\left(\frac{8503}{T}\right)$$

where the concentrations are expressed in mol/m<sup>3</sup>. This study showed unambiguously that  $CH_4$  inhibits  $O_2 + MMH (+Ar)$  ignition. This inhibiting effect depends on the mixture composition (equivalence ratio in MMH,  $[MMH]/[CH_4]$  ratio, etc.), on the temperature, and on the pressure. From a mechanistic point of view, methane is supposed to compete with MMH decomposition products for reaction with oxygen. The comparison between the  $O_2/CH_4/Ar$  and  $O_2/CH_4/MMH/Ar$  ignition delays led to the conclusion that MMH can be used as an ignition promoter in  $O_2/CH_4$  mixtures.

#### 4.1.6 Computational Chemistry Calculations of MMH Decomposition Kinetics

The reaction kinetics for the thermal decomposition of MMH were studied using quantum mechanical theory [258]. Thermochemical properties were determined by *ab initio* and DFT calculations. The entropies  $S^\circ$  and heat capacities  $C_p^\circ$  from vibrational, translational, and external rotational contributions were calculated using statistical mechanics based on the vibrational frequencies and structures obtained from the density functional study. Potential barriers for internal rotations were calculated, and hindered rotational contributions to  $S^\circ$  and  $C_p^\circ$  were calculated by solving the Schrödinger equation with free rotor wave functions, and the partition coefficients were treated by direct integration over energy levels of the internal rotation potentials. Enthalpies of formation  $\Delta H_f^\circ$  for the parent  $\text{CH}_3\text{NHNH}_2$  molecule and its corresponding radicals  $\text{CH}_3\text{N}^\bullet\text{NH}_2$ ,  $\text{CH}_3\text{NHN}^\bullet\text{H}$ , and  $^\bullet\text{CH}_2\text{NHNH}_2$  were determined to be 90.4, 203, 214, and 263 kJ/mol (21.6, 48.5, 51.1, and 62.8 kcal/mol) by use of isodesmic reaction analysis and various *ab initio* methods. A kinetic analysis of the thermal decomposition, abstraction, and substitution reactions of MMH was performed, with those of N—N and C—N bond scissions determined by high-level calculations. Rate constants of thermally activated MMH going to dissociation products were calculated as functions of pressure and temperature. An elementary reaction mechanism based on the calculated rate constants, thermochemical properties, and literature data was developed to model the experimental data on the overall MMH thermal decomposition rate. The reactions of N—N and C—N bond scission were found to be the major reaction paths for the modeling of MMH homogeneous decomposition under atmospheric pressure conditions.

The decomposition kinetics of MMH were studied with *ab initio* transition state theory-based master equation analyses [269]. The simple N—N and C—N bond fissions to produce the radicals  $\text{CH}_3\text{N}^\bullet\text{H} + ^\bullet\text{NH}_2$  or  $^\bullet\text{CH}_3 + ^\bullet\text{NHNH}_2$  were expected to dominate the decomposition kinetics. The transition states for these two bond fissions were studied using variable reaction coordinate transition state theory employing directly determined interaction energies. The transition state theory analysis provided high pressure dissociation and recombination rate coefficients. Predictions for the pressure dependence and product branching in the dissociation of MMH were obtained by solving the master equation.

Methylamine radicals ( $\text{CH}_3\text{N}^\bullet\text{H}$ ) and amino radicals ( $^\bullet\text{NH}_2$ ) are the major products in the early ignition/pyrolysis of MMH. The kinetics of the thermal decomposition of  $\text{CH}_3\text{N}^\bullet\text{H}$  radicals were analyzed using master equation analysis [270]. It was found that  $\beta$ -scission of the methyl H atom from  $\text{CH}_3\text{N}^\bullet\text{H}$  radicals is dominant and fast enough to induce subsequent H-abstraction reactions to trigger ignition. The gas-phase kinetics of H-abstraction reactions from  $\text{CH}_3\text{NHNH}_2$  by H atoms was further investigated by *ab initio* second-order multi-reference perturbation theory and quadratic configuration interaction calculations. The rate coefficients for each of the abstraction channels were quantified by micro-canonical transition state theory, and the associated branching ratios determined. It was found that the total rate coefficient determined from

*ab initio* kinetics theories was in excellent agreement with the experimental value observed at room temperature. Thus, the theoretical rate coefficients from this work should be reliable over a wide temperature range and are essential parameters in the development of reaction mechanisms for the kinetics modeling of ignition involving MMH.

The thermal decomposition of the  $\text{CH}_3\text{N}^\bullet\text{NH}_2$ , *cis*- $\text{CH}_3\text{NHN}^\bullet\text{H}$ , *trans*- $\text{CH}_3\text{NHN}^\bullet\text{H}$ , and  $\text{C}^\bullet\text{H}_2\text{NNH}_2$  radicals, which are the four radical products from the H-abstraction reactions of MMH, were theoretically studied by using *ab initio* transition-state theory and master equation analysis [271]. Various decomposition pathways were identified by using various quantum chemistry methods. The study revealed that the  $\beta$ -scission of  $\text{NH}_2$  to form methylene imine is the predominant channel for the decomposition of the  $\text{C}^\bullet\text{H}_2\text{NNH}_2$  radical owing to its small energy barrier of 57.7 kJ/mol (13.8 kcal/mol). The calculated rate coefficients associated with updated thermochemical property data are essential components in the development of kinetic mechanisms for the pyrolysis and oxidation of MMH and its derivatives.

The mechanisms of multi-channel reactions between methylhydrazines and atomic hydrogen:

and

have been investigated by computational chemistry, and the dynamic properties were studied using a dual-level direct dynamics method [272]. The electronic structures and energies of the stationary points were calculated by the combination of various methods and basis sets. The rate constants of reactions in a temperature range of 200–2000 K were evaluated by using the canonical variational transition state theory with a small-curvature tunneling correction. The effect of treating torsional anharmonicity with different models on the rate constants was compared. Theoretical and experimental studies indicated that substitution of H by  $-\text{CH}_3$  groups on  $\text{H}_2\text{NNH}_2$  leads to a significant increase in rate coefficients. The kinetic isotope effects were studied for both the methylhydrazine(s) with hydrogen/deuterium and the MMH/deuterated MMH with hydrogen atom.

Mass spectrometric observations in a very-low-pressure pyrolysis study [252] of the decomposition of MMH had already indicated a dominant role for the molecular channels producing  $\text{NH}_3$  and  $\text{H}_2$  and their coproducts. In contrast, an *ab initio* transition state theory-based master equation theoretical study [269] predicted that simple N–N and C–N bond fissions would dominate the kinetics. The possible role of molecular decomposition channels in MMH was explored further through additional investigations of the potential energy surface [260]. These investigations considered the role of triplet channels, of roaming radical channels, and of some previously unexplored pathways for molecular decomposition. New *ab initio* transition state theory-based

master equation calculations provided revised predictions for the temperature and pressure dependence of the MMH decomposition kinetics that were in full agreement with shock tube measurements [261]. These calculations suggested only a very limited contribution from the molecular elimination channels. A roaming pathway was suggested to provide the dominant route for direct formation of ammonia. There is a possible role of secondary abstraction reactions in the very-low-pressure pyrolysis experiments.

## 4.2 Catalytic Decomposition of Liquid MMH

If excess liquid MMH is allowed to contact hydrazine decomposition catalysts at room temperature, a slow reaction with gas evolution ensues, but spontaneous ignition does not take place as in the case of hydrazine. The composition of the gases is essentially independent of the type of catalyst (Girdler G-22, Engelhard MFSA-4A, or Shell 405), consisting of (all numbers in mol-%) 0.2 H<sub>2</sub>, 39–43 CH<sub>4</sub>, 52–60 N<sub>2</sub>, and 0.4–3 C<sub>2</sub>H<sub>6</sub> [206].

## 4.3 Photolysis of MMH

In order to study the environmental fate of MMH vapors that have escaped into the air, it is necessary to know the conditions that will lead to photolysis of MMH, what the half-life time of MMH vapor is in intense sunlight, and what its photolysis products are. The same photolysis mechanism, sometimes in combination with ozonization, can be used with advantage in treatment of waste waters from rocket test sites and decontamination of propellant spills.

The gas-phase photochemistry of MMH photolysis has been studied in UV at 298 K [167]. Relative UV absorbance spectra of dilute mixtures of MMH in He buffer gas were recorded in the region 140–310 nm with an instrument resolution of 0.25 nm. These absorbance spectra were converted to absolute absorption cross-section profiles by scaling the data with absolute 253.65-nm cross-section values of  $\sigma_{253.65} = (8.022 \pm 0.481) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  for MMH. Both MMH and UDMH exhibit continuous diffuse absorption bands in UV that correspond to electronic transitions to dissociative singlet excited states. Laser photodissociation product measurements revealed the absolute H atom primary quantum yields to be  $\Phi_{248} = 1.07 \pm 0.02$ ,  $\Phi_{222} = 0.99 \pm 0.01$ , and  $\Phi_{193} = 0.94 \pm 0.07$  for MMH photolysis at 248, 222, and 193 nm respectively. Kinetic measurements gave the absolute second-order H atom rate coefficients to be  $k = (7.60 \pm 1.14) \times 10^{-13}$  for reactions with MMH at 298 K diluted in 26.0 mm Hg of He.

#### 4.4 Radiolysis of MMH

Methylhydrazine fuel in satellites and space probes is subjected to intense cosmic radiation. Long-term radiolysis by hard gamma rays that can penetrate propellant tank walls would result in deterioration of MMH fuel quality and may result in undesirable pressure buildup in hermetically sealed tanks. Solar cosmic rays have a high-energy proton component. Satellites in the van Allen belt around Earth and in the radiation belt around Jupiter are subjected to intense radiation that may cause propellants to decompose. On long-term deep-space missions, Radioisotope Thermal Generators (RTGs) provide electric power from the heat generated by the decomposition of radioactive isotopes. Although RTGs are shielded and placed on extendable booms away from the spacecraft core, some radiation penetrates the shielding. Propellant tanks in the vicinity of RTGs are still subjected to nuclear radiation. Because oxidizers are less sensitive to radiation damage than fuels, it would be best to design the spacecraft such that the oxidizer tank is between the radiation source and the fuel tank.

Both the US and the former USSR have flown satellites with nuclear fission reactors such as SNAP-8 as powerplants. Some of these satellites may have used NTO/MMH thrusters for attitude control, orbit adjustment, and controlled de-orbit. The propellant tanks may not have been shielded from the nuclear reactors.

In an atomic war battle field situation, missiles with MMH fuel tanks may be subjected to intense neutron radiation that would alter propellant properties or cause premature decomposition. For all these reasons, radiolysis of MMH has been studied extensively in the past.

A radiation test was conducted on 98.7% MMH/1.3% H<sub>2</sub>O to evaluate the effects of reactor radiation on (1) the hypergolicity of this material with dinitrogen tetroxide as the oxidizer, and (2) the off-gas evolution leading to pressure buildup in the tank [273]. In addition, the effects of radiation on viscosity, density, melting point, and MMH assay were also measured. Samples of MMH were exposed to an integrated flux of approximately  $5 \times 10^{15}$  nvt ( $E > 0.5$  MeV) =  $5 \times 10^{15}$  n/cm<sup>2</sup> fast neutrons at a flux rate of  $2 \times 10^{10}$  n cm<sup>-2</sup> s<sup>-1</sup>, and a total dose of  $1 \times 10^8$  r. Based on measurements of ignition time delay, this exposure produced no significant effect on the hypergolicity of MMH when injected with NTO. However, a significant off-gas pressure developed that was a linear function of the radiation exposure above  $10^6$  r. After exposure to  $1 \times 10^8$  r, the off-gas volume (at 1 atm, and 298 K = 77 °F) was 21 mL gas per milliliter of liquid. The chromatographic analysis of the off-gas showed it to be a mixture of approximately 28 mol-% hydrogen, 41 mol-% nitrogen, and 31 mol-% methane with minor amounts of oxygen, ammonia, and monomethyl hydrazine vapor. The irradiated liquid material exhibited a 4.5% decrease in MMH assay, a 5.5% increase in viscosity, and a 0.9% increase in density. The melting point was unaffected by radiation.

Investigations were made of the possibility of suppressing the generation of non-condensable gases when MMH was subjected to ionizing radiation from cobalt-60 with and without free-radical scavengers [274, 275]. MMH produced more than twice its vol-

ume of gas (measured at 298 K = 25 °C and 101 kPa = 1 atm) consisting of hydrogen, nitrogen, and methane when irradiated to nearly  $10^7$  r with gamma rays. An attempt at gas suppression was made with chemical additives that could scavenge free radicals by reacting with them. Free radical scavengers had no effect on decomposition, indicating a molecular or ionic decomposition reaction rather than a free-radical mechanism. Two normally efficient olefinic additives (free-radical scavengers such as methyl methacrylate or pentadiene-1,3) failed to suppress gas evolution, thereby demonstrating that MMH does not decompose radiolytically via free-radical intermediates. Instead, MMH decomposes via a molecular or ionic process. The addition of carbon tetrachloride as a potential, gas suppressing additive actually increased gas evolution enormously, and this can be explained on the basis that it initiates a chemical chain reaction. The storability of MMH with respect to solar, cosmic, van Allen belt, and nuclear fission reactor radiation cannot be improved by the addition of free-radical scavengers as the scavengers fail to suppress the generation of off-gases in MMH by the radiation. Accordingly, the radiolytic decomposition of MMH proceeds via a molecular or ionic reaction rather than a diffusion-controlled, free-radical reaction. Gamma radiolysis of a 100-mL specimen of MMH to  $8.5 \times 10^6$  r produced 227 mL of off-gas (at 298 K and 101 kPa), which was nearly an equimolar mixture of hydrogen (38.7%), nitrogen (33.5%), and methane (27.8%). The average radiation yields (molecules/100 eV) of these gases were 4.7, 4.0, and 3.4 respectively.

Similar radiolysis measurements were made for UDMH [276] and Aerozine-50. See also [277, 278]. A summary was given of propellant radiation damage as a function of source type and mission. It was concluded that  $\alpha$ -heat sources such as  $^{238}\text{Pu}$  or  $^{244}\text{Cm}$  probably would not require additional shielding to protect the propellants, even with large power sources.  $\beta$ - and  $\gamma$ -radioisotope sources and nuclear reactor sources will most likely require propellant-shielding on long missions.

#### 4.5 Electron Bombardment Decomposition of MMH

The most common place for electron bombardment (electron impact) decomposition of MMH to take place is in the inlet to mass spectrometers, where the neutral molecules are ionized so that they can be separated by mass and electric charge in crossed electric and magnetic fields in the mass spectrometer.

Electron bombardment ionization thresholds give information on the ionization energy and bond dissociation energies of molecules. An alternate way of achieving ionization would be by UV radiation photolysis with light of different wavelengths. Dissociative ionization cross-sections, fragment appearance potentials, and fragment kinetic energies were measured for electron-impact excitation of jet-cooled MMH over an energy range of 10–270 eV and the data were entered into a data base containing 35 parent and fragment ions [279, 280]. All measurements were made in a crossed electron-molecular beam apparatus using pulsed extraction and time-of-flight mass de-

tection to ensure field-free excitation and high collection efficiency for energetic ions. The measured MMH cross-sections for total ionization at 70 eV were  $4.20 \text{ \AA}^2$ . High-resolution mass spectra were recorded for MMH in order to distinguish different fragment ions of the same unit mass. Substantial rearrangement was evident for  $\text{N}_2\text{H}_4$  and MMH dissociative ionization based on the appearance of ions such as  $\text{NH}_3^+$  and  $\text{NH}_4^+$ .

The dissociation of methylated hydrazine ions was observed to undergo extensive fragmentation and rearrangement leading to many fragments that have the same nominal mass, but differ in chemical composition by an N versus  $\text{CH}_2$  moiety. Previously, absolute ionization cross-sections were measured for hydrazine and MMH dissociative ionization using a high throughput time-of-flight mass spectrometer that had excellent detectability of high kinetic energy ions, but only moderate mass resolution (0.1 amu). Improved high-resolution quadrupole detection (0.005 amu) allowed one to distinguish ion fragments of the same nominal mass for MMH and UDMH [281]. The ratios of these close-lying fragment masses were measured for different electron impact energies and explained in terms of thermochemical thresholds and fragmentation mechanisms. The methyl groups account for complex reaction mechanisms. A high yield was observed for NH dissociation induced by a 1,2 sigmatropic hydride shift and for  $\text{CH}_4$  dissociation formed by a 1,2 elimination. Some fragmentation reactions involved large activation energies or unusual mechanisms.

## 4.6 Reactions of MMH

Methylhydrazine is one of the more reactive rocket fuels, and a complete account of all reactions it can enter into would fill a book in its own right. The following sections summarize reactions that relate to storability, contamination, explosion hazards, and safety properties of MMH.

### 4.6.1 Reactions of MMH with Inorganic Compounds

#### 4.6.1.1 Reactions of MMH with Oxygen

Oxygen is everywhere on Earth where MMH may be handled. Typically, one avoids contact between MMH and oxygen in air by keeping a nitrogen pad at a slightly positive pressure above MMH stored in shipping containers and storage tanks. Often, facility nitrogen that is plumbed in at rocket test sites contains traces of oxygen contamination. Even ppm levels of oxygen react with MMH. Kinetics of gas-phase reactions of MMH with  $\text{O}_2$  were already discussed in Section 4.1.5 in conjunction with shock tube studies of MMH vapor decomposition. Here, we discuss reactions of oxygen with MMH at low partial pressures, autoxidation conditions that do not lead to ignition. Ignition of MMH in air or oxygen is discussed in Section 10.2. Rocket engines operating on LOX and MMH will be discussed in a future set *Encyclopedia of Non-Hypergolic Bipropellant Combinations*. Atmospheric decay of MMH is discussed in Section 12.3.

The autoxidation of MMH was studied in a 300-mL and a 12-L Pyrex flask, at a partial pressure of 5 mm Hg in a 44-cm path length IR spectrophotometer cell, and in a long path reaction cell constructed from a  $0.152 \times 3.05$ -m section of Pyrex pipe [282]. The half-life of MMH was 2–7 h depending on reaction vessel surface area and activity. Possible mechanisms were difficult to postulate, but the overall reaction was:

with the formaldehyde methylhydrazone condensing out as a polymer oil. Similar tests were conducted using hydrazine and UDMH vapors.

#### 4.6.1.2 Reactions of Methylhydrazines with Atomic Oxygen

Collision cross-sections were measured for MMH reactions with  $\text{O}^+$ ,  $\text{CO}^+$ ,  $\text{CO}_2^+$ , and  $\text{NO}^+$  at suprathermal collision energies ranging between 1 and 20 eV (center of mass) in an octopole guided-ion-beam apparatus [283]. Dissociative charge transfer occurred in each reaction, similar to reactions involving hydrazine. The total reaction cross-section was on the order of  $50\text{--}100 \text{ \AA}^2$ , and the amount of  $\text{CH}_3\text{NHNH}_2^+$  fragmentation in each case depended upon both the exothermicity of the charge transfer and the availability of internal degrees of freedom in the incident primary ion.

In low Earth orbit, atomic oxygen collides with plume/exhaust species with a relative velocity around 8 km/s. The several electron volts of kinetic energy in the collision can transfer energy into IR-emitting states of the plume species and can open chemical reaction pathways that are not available under thermal conditions.

Emissions of  $\text{CHA} \rightarrow \text{X}$ ,  $\text{CNB} \rightarrow \text{X}$ , and  $\text{NHA} \rightarrow \text{X}$  transitions within the range 325–440 nm caused by the reaction of fast  $\text{O}(^3\text{P})$  atoms with hydrazine, MMH, or UDMH in gas-phase collisions were observed using a crossed-beam molecular beam apparatus [284]. Many experiments have been plagued by uncertainties about the quality of the atomic oxygen stream used, which may have contained excited oxygen or molecular dinitrogen instead of pure atomic oxygen in the ground state. The  $\text{O}(^3\text{P})$  resonance fluorescence technique unambiguously provides a stream of atomic oxygen in the ground state by using a pulsed  $\text{F}_2$  laser emitting at 157 nm to photolyze the  $\text{O}_2$ . The reaction rates can be measured accurately by the decay of 131 nm  $\text{O}(^3\text{S} \rightarrow ^3\text{P})$  resonance fluorescence under both high pressure (6.6 kPa) and low pressure (133–350 Pa) conditions [285, 286]. The measured rate constants are summarized in Table 31.

The ratio of the rate constants is close to that of the number of hydrogen atoms in these three molecules. It cannot be proven that the mechanism is one of hydrogen abstraction, but it looks that way.

The gas-phase kinetics of  $\text{O}(^3\text{P})$  and OH reactions with MMH or UDMH were studied in a discharge flow-tube apparatus [287, 288]. The reactions were studied in 267 Pa (2 mm Hg) of He dilution under pseudo-first-order conditions in the transient species concentration with a known excess of hydrazine concentration. The steady-state concentration temporal profiles of the transient species were directly monitored using flu-

**Table 31:** Rate constants of reactions of atomic oxygen with hydrazines at 296 K.

| Fuel      | Rate constant, $\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ | Ratio (normalized by $\text{N}_2\text{H}_4$ rate) | Ratio of number of hydrogen atoms | Number of hydrogen atoms |
|-----------|-------------------------------------------------------------------|---------------------------------------------------|-----------------------------------|--------------------------|
| Hydrazine | $0.99 (\pm 0.12) \times 10^{-11}$                                 | 1.0                                               | 1.0                               | 4                        |
| MMH       | $1.6 (\pm 0.34) \times 10^{-11}$                                  | 1.6                                               | 1.5                               | 6                        |
| UDMH      | $2.3 (\pm 0.34) \times 10^{-11}$                                  | 2.3                                               | 2.0                               | 8                        |

Data source: [285, 286]

orescence techniques to deduce the absolute second-order reaction rate coefficients. The Arrhenius expression:

$$(2.71 \pm 0.04) \times 10^{-11} \exp(190 \pm 50)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

within the temperature range 252–640 K was obtained for reactions of  $\text{O}(^3\text{P})$  with MMH. The corresponding expression:

$$(2.88 \pm 0.04) \times 10^{-11} \exp(210 \pm 55)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

within the range 232–374 K was determined for the  $\bullet\text{OH}$  reaction with MMH. Alkylation in the hydrazine molecule allows direct H-abstraction mechanisms to operate in these reaction systems.

In a later study [288] with direct laser-induced fluorescence monitoring of the  $[\text{OH}]$  temporal profiles in a known excess of MMH yielded the following absolute second-order OH rate coefficient expression:

$$k_1 = (4.59 \pm 0.83) \times 10^{-11} \exp(85 \pm 35)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

for reactions with MMH within the temperature range 232–637 K.

The gas-phase reaction kinetics of O atoms with MMH was studied in a discharge flow-tube apparatus under pseudo-first-order conditions in  $[\text{O atom}]$  [289, 290]. Direct VUV CW-resonance fluorescence monitoring of the  $[\text{O atom}]$  temporal profiles in a known excess of MMH yielded the following absolute second-order O atom rate coefficient expression within the temperature range 232–644 K and under He pressure of 2.0 Torr:

$$k_1 = (2.29 \pm 0.40) \times 10^{-11} \exp(-145 \pm 40)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

The modeling of UV radiation from high-altitude plumes containing MMH or UDMH was compared with observed data from the MIR space station [291].

#### 4.6.1.3 Shock Tube Studies of MMH Combustion and Detonation Kinetics

The ignition delays  $\tau$  of MMH decomposition products were measured behind a reflected shock wave at 900–1440 K, 160–350 kPa, fuel:oxidizer equivalence ratios from 1 to 2.27, and argon diluent molar fractions from 0.82 to 0.96 [292]. The MMH absorption at 220 nm was taken as an indication of MMH concentration in the

reacting mixture. A kinetic model/computer program was developed that included 300 individual reactions and that reproduced the experimental results quite well ( $\pm 35\%$ ) within the ranges 1070 to 1260 K and 190 to 290 kPa. Plotting an ignition delay function (a logarithm of  $\tau$ ) vs.  $1/T$  allowed the determination of the activation energy (it was of the order of  $99 \pm 3$  kJ/mol). If the ignition delay is sufficiently reduced by approaching stoichiometric ratios or applying less diluent, then a detonation wave can be initiated behind the incident shock. Detonation velocity of ternary  $O_2$ /MMH/ $N_2$  mixtures was measured both by equally spaced, directly inserted pressure probes and by measuring the cell size on smoked witness tubes. The critical conditions for a self-sustained detonation were bracketed by a series of experiments. The detonation velocity of 52.4 mol%  $O_2$ /47.6% MMH (equivalence ratio  $\phi = 2.27 =$  fuel rich) at an initial pressure of 2 kPa was 2400 m/s once the initiating shock wave from a bursting diaphragm in a helium-filled donor section (He fill pressure varied from 0.4 to 0.7 MPa) was energetic enough. This value was below that predicted from C-J calculations for this mix. Surprisingly, cell size vs. pressure plots showed that stoichiometric  $O_2$ /MMH mixtures were less detonable than  $O_2$ /UDMH or  $O_2$ / $N_2H_4$  mixtures. It was not possible to establish a simple correlation between the detonation cell size and the induction distance for the explosive oxidation calculated from ignition delay data.

The fundamental gas-dynamic characteristics of the detonation, instantaneous combustion (explosion) in constant volume, combustion at constant pressure, and deflagration for hydrazine, MMH, UDMH, SDMH, or trimethylhydrazine in mixtures with oxygen or air that are diluted with argon at varied initial pressure and temperature values were examined [293, 294]. Spray detonation is also potentially relevant to the study of pulse detonation engines and other hypersonic propulsion systems exploiting detonative reactions. The main parameters of these processes were analyzed both for the case of a gaseous propellant and for the case of a heterogeneous propellant where the propellant is a highly disperse, sprayed aerosol cloud in an oxidant medium. Calculations were performed by means of the computer code SAFETY. Calculation results were in agreement with experimental data. For MMH vapor, detonation wave velocity was predicted to be  $D_0 = 1941$  m/s. For a stoichiometric mixture of MMH vapor with oxygen the detonation wave velocity was predicted to be  $D_0 = 2476$  m/s. For a stoichiometric mixture of MMH vapor with air the detonation wave velocity was predicted to be  $D_0 = 1894$  m/s. A poorly dispersed spray of liquid MMH aerosol in a stoichiometric proportion to oxygen was predicted to detonate with  $D_0 = 1848$  m/s.

Ignition delay times for MMH/ $O_2$ /Ar gaseous mixtures have been modeled by a reaction scheme containing 70 species and 373 equilibrated elementary reactions [267]. For many reactions, the rate constants had to be estimated or adjusted because rate constants were available for only a few reactions. Results of measurements of ignition delay times behind reflected shock waves performed over a range of temperatures, pressures, and compositions were compared with computed predictions. Good agreement between measured and calculated ignition delay times was obtained,

but only for lean and less dilute mixtures. The reaction most likely begins with the scission of the N—N bond in MMH, but elimination reactions from MMH also have to be considered, especially at a high initial temperature. The  $\text{NH}_2$  radicals formed can react with MMH to give  $\text{CH}_3\text{NNH}_2$  radicals and products. These radicals react with  $\text{O}_2$  to produce methyldiazene ( $\text{CH}_3\text{N}=\text{NH}$ ) and  $\text{HO}_2$  radicals.  $\text{HO}_2$  radicals react with MMH to give  $\text{CH}_3\text{NNH}_2$  radicals and  $\text{H}_2\text{O}_2$ , which plays a major role through its thermal decomposition, which produces more hydroxyl radicals.

#### 4.6.1.4 Slow Autoxidation of MMH Vapors in the Atmosphere

Exposure of MMH to air may be difficult to avoid during propellant transfer, in particular when venting the source tank after the transfer is complete. The slow reaction of MMH with oxygen was noticeably exothermic. Gas chromatographic analysis of the liquid reaction product after 24 h showed the presence of ten components, including methanol, MMH, *sym*-hexahydro-1,4-dimethyltetrazine, and water. The cytostatic action of MMH derivatives has been linked to the formation of peroxides or even free OH radicals during the biological oxidation of these compounds in cancer tissue [295]. The oxidation is catalyzed by  $\text{Cu}^{2+}$  ion and inhibited by complexing of Cu with EDTA, DNA, or pyrophosphate.

The reactions between MMH and molecular oxygen in the gas phase have been studied in three separate experiments [230, 235]. The results indicated that at room temperature the reaction is stoichiometric and that methyldiazene  $\text{CH}_3\text{N}=\text{NH}$  is the initial product. The reaction was complete in a matter of minutes. At 592 K (319 °C), in an experiment in which the initial  $\text{O}_2$  : MMH ratio was 1 : 6, all of the MMH disappeared with a surprisingly large quantity of hydrogen as a product. A chain-type process, possibly explosive, was implicated.

The level of trace organic impurities in MMH is a function of the handling history of the MMH sample. Atmospheric oxygen was responsible for the changes, and methane (<100 ppm), ethane (<50 ppm), and AM (<50 ppm) were found to be oxygen-generated [234]. SDMh was a possible but unconfirmed impurity.

In studying the autoxidation of MMH at room temperature in the gas phase, the objective was to characterize the lifetime of MMH mixed with  $\text{O}_2$ , both reactants in the gas phase, at 295 K in a 10-L spherical Pyrex vessel with a surface-to-volume ratio of  $22.4\text{ m}^{-1}$  and two different oxygen : MMH molar ratios of 2.52 (equivalence ratio = 0.99) and 6.4 (equivalence ratio = 0.39) [296]. The reaction was followed principally by IR spectroscopy over the mid-IR region ( $4000$  to  $500\text{ cm}^{-1}$ ) at  $4\text{ cm}^{-1}$  resolution. Figure 28 shows the changes in the IR spectrum with time for the experiment with an oxygen : MMH ratio of 6.4.

The spectrum at  $t = 0$  is that of pure gaseous MMH. The disappearance of MMH was obvious as some MMH bands disappeared and some new IR features became evident. The  $\text{O}_2$  : MMH equivalence ratio had no effect on the changes. The MMH bands that clearly disappeared were those centered at  $779\text{ cm}^{-1}$  (NH bending at  $777\text{ cm}^{-1}$ ), and those centered at  $900\text{ cm}^{-1}$  ( $\text{NH}_2$  rocking at  $888\text{ cm}^{-1}$ ), indicating that the  $-\text{NHNH}_2$

**Figure 28:** Progressive changes in the infrared spectrum of methylhydrazine vapor during autoxidation. (Reprinted and modified from [296], with permission by ©2000 Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

structure as encountered in MMH no longer existed. The new IR features indicate the formation of methane ( $3016$  and  $1304\text{ cm}^{-1}$ ). Some other features were attributed to methanol ( $2960$ ,  $1477$ ,  $1345$ , and  $1033\text{ cm}^{-1}$ ). The formation of methyldiazene was not obvious when comparing the IR spectrum of this molecule with the spectra of the reaction products. Mass spectra of the reaction products did not clearly identify any of the products because many peaks overlapped with  $m/e$  of  $\text{O}_2$ ,  $\text{CO}_2$ , and  $\text{H}_2\text{O}$ .

A detailed kinetic model has been built to allow a numerical study of the slow homogeneous MMH/ $\text{O}_2$  reactivity. A kinetic model of this type is also useful for modeling the faster oxygen/MMH reaction leading to ignition and for explaining the ignition delay if such mixtures are rapidly heated in a shock tube. The ignition of oxygen or air mixtures with MMH vapors is discussed in a future *Encyclopedia of Non-Hypergolic Bipropellant Combinations*. This property also affects the flash point or auto-ignition temperature of MMH in air (Section 10.1).

The autoxidation of 4.6% MMH vapor in air in 320-mL glass or polyethylene flasks led to nitrogen and methane [297, 298]. In glass, the half-life time was 34 min.

In polyethylene the reaction was much faster and was complete in 10 min, indicating a surface catalytic effect. The reaction was designated as first order in MMH and zero order in oxygen despite the non-linearity of the  $\ln([MMH]/[MMH]_0)$  vs. time plot at long reaction times. The authors should have spent a little more time explaining this non-linearity. Exposure of MMH liquid to air for only brief periods changed the amounts of trace impurities (methane, AM, SDMH). With monitoring of the MMH/O<sub>2</sub> reaction in an IR spectrometer, the major MMH peaks at 11.2 and 12.9  $\mu\text{m}$  diminished steadily throughout the first several scans and almost disappeared after 10 min [230]. An intermediate peak at 11.8  $\mu\text{m}$  has been assigned to methyldiazene. It peaked after 10 min and then gave way to an increasing methane peak at 7.6  $\mu\text{m}$ . The following mechanism has been proposed:

Subsequently, CH<sub>3</sub>N=NH has also been discovered as a peak at  $m/e = 44$  when extracting a sample from a reacting mixture of 4-kPa (30-mm-Hg) MMH and 2-kPa (15-mm-Hg) O<sub>2</sub> directly into a quadrupole mass spectrometer. This technique also confirmed the slow increase of SDMH at  $m/e = 60$ . It is possible that SDMH is a daughter product of methyldiazene decomposition. With additional oxygen, SDMH then becomes oxidized to AM. When adding AM to MMH in sealed tubes in molar ratios of AM : MMH = 1 : 5 and 1 : 25, each AM molecule destroyed only one MMH molecule in a stoichiometric reaction. Although AM is a radical source for the initiation of radical chain reactions (e.g., polymerizations), the decomposition of MMH does not appear to be a chain reaction.

Studying the autoxidation of MMH or other hydrazines in confined atmosphere chambers is difficult. MMH and oxygen may diffuse through thin plastic walls. Metal walls may catalyze autoxidation [299].

Air and oxygen oxidation studies of 1 mL of MMH injected and vaporized into a 300-mL Pyrex flask at 81-kPa (610-Torr) helium/13.3-kPa (100-Torr) oxygen pressure showed that all oxygen is consumed within 100 min. Nitrogen and methane are found as reaction products [282]. Tests with a larger (12-L) Pyrex vessel gave identical results. Reaction IR spectroscopy in a 44-cm pathlength cell gave even more detailed kinetic data. A number of changes in spectral features are apparent while the reaction is in progress. The N—H stretching band at 3260  $\text{cm}^{-1}$  decreased after 6 h and disappeared entirely after 23 h. A new band at 3080  $\text{cm}^{-1}$  became visible after 6 h and was very strong at 23 h. Similar tests with a 2.75-m-long 55-L cell with a multiple reflection (pathlength 200 m) even allowed the early detection of trace quantities of short-lived intermediates and oxidation products. One transient intermediate absorbing at 846  $\text{cm}^{-1}$  was not identified. MMH oxidation in synthetic air proceeds with a half-life of 2–7 h depending on vessel surface area and material. Heterogeneous processes are

probably dominant, in particular at higher concentrations. The stoichiometry can be approximated by:

The formaldehyde methylhydrazone condenses out as a polymer oil. Additional FTIR studies in a 60-L cell consisting of a 6-in by 10-ft section of Pyrex pipe with an effective pathlength of 200 m showed that the autoxidation of 25 ppm MMH in 80% helium/20% oxygen leads to intermediate production of methane, methanol, and methyldiazene [300]. After 74 h, only methane and some unidentified contaminants remained. The half-life time for MMH under these conditions was approximately 250 min.

It was difficult to study the autoxidation of hydrazines in Teflon-lined chambers because diffusion of MMH vapors through the Teflon foil and intrusion of ambient air oxygen through the Teflon foil interfered with the autoxidation measurements [301].

Methylhydrazine–air autoxidation studies on materials of construction in powder form in a tubular reactor at 328 K resulted in methanol, methyldiazene, methane, and, occasionally, traces of ammonia [302–304]. The overall reactivity order of the catalysts for the air oxidation of MMH was  $\text{Fe} > \text{Al}_2\text{O}_3 > \text{Ti} > \text{Zn} > \text{CRES-316} > \text{Cr} > \text{Ni} > \text{Al} > \text{CRES-304}$ . In this apparatus, di-, tri-, and tetra-methylhydrazines were much less reactive than hydrazine or MMH.

The autoxidation of MMH in the gas phase was studied in a strictly single-phase gaseous medium, in a reconstituted synthetic atmosphere [305]. The reaction kinetics was studied at 323 K (50 °C) to avoid condensation of the water formed and for  $\text{O}_2$ /MMH molar ratios between 1 and 4. Under these conditions, the partial pressures of  $\text{O}_2$  were between 0.05 and 0.18 bar (4% MMH per volume). The main reaction products were monitored through time and identified by GC-MS. The products were:  $\text{N}_2$ ,  $\text{CH}_4$ ,  $\text{H}_3\text{CNH}-\text{N}=\text{CH}_2$  (formaldehyde monomethylhydrazone),  $\text{NH}_3$ ,  $\text{H}_2\text{O}$ ,  $\text{CH}_3\text{OH}$ , and  $\text{H}_2\text{C}=\text{N}-\text{N}=\text{N}-\text{CH}_3$  (2,3,4-triazapenta-1,3-diene). The formation of nitrosamines was not observed under these experimental conditions. The rate laws related to the disappearance of the reactants were clearly established and could be described by two consecutive parallel reactions of second order whose rate constants were:  $k_1 = 7.57 \times 10^{-2} \text{ bar}^{-1} \text{ min}^{-1}$  and  $k_2 = 0.5 \text{ bar}^{-1} \text{ min}^{-1}$ . Analysis of the products permitted an approximated balance of the global reaction to be established.

#### 4.6.1.5 Autoxidation of MMH in the Liquid State

When dry oxygen was bubbled through liquid MMH for 21 days, the condensate in a 193-K cold trap contained methyl azide, ammonia, and methylamine [306]. Methyl azide formation has also been observed during the autoxidation of UDMH [307]. In a similar test, ambient air was bubbled through MMH to create artificially aged MMH and the NVR was analyzed [308].

#### 4.6.1.6 Autoxidation of MMH in Solution

The autoxidation of MMH by dissolved air in aqueous solution is an important process if one has to determine the longevity of MMH spills in clean surface waters without soil contact or suspended sediments. This information is needed for the design of wastewater treatment plants for waste water drained from rocket test sites.

The rate of oxidation of hydrazines (hydrazines spilled into surface water) was measured by pouring a measured amount of hydrazine, MMH, or UDMH into 2 L of distilled air-saturated water in a glass flask and measuring pH and dissolved oxygen as a function of time [309]. The starting concentration of dissolved oxygen was typically above 7.5 ppm. MMH concentrations from 220 to 880 mg/L and UDMH at concentrations from 200 to 800 mg/L were studied for rate of oxidation. In some experiments, controlled amounts (0.125, 0.25, 0.5, and 1.0 mg/L) of copper  $\text{Cu}^{2+}$  ion were added to test its effectiveness as a catalyst. In the sample containing the highest  $\text{Cu}^{2+}$  addition, dissolved oxygen dropped from 7 to 0.3 ppm in less than 1 min. No effort was made to exclude ambient air during the experiment, but as the experiments were short, reabsorption of oxygen from the air could be neglected. Besides, in free nature, additional oxygen from the air would also be available to aid degradation of hydrazines in the water. The data giving the rate of disappearance of oxygen and hydrazine were curve-fitted to a kinetic model with empirical constants of the type:

$$\frac{d(\text{DO})}{dt} = -\frac{k}{V}(\text{DO})^n$$

where DO is dissolved oxygen,  $k/V$  is an average rate constant, and  $n$  is the average order of the reaction. Results for hydrazine, MMH, and UDMH are shown in Table 32.

**Table 32:** Autoxidation of hydrazines (in the absence of copper ions).

| Propellant | Average order $n$ | Average rate constant, L/min |
|------------|-------------------|------------------------------|
| Hydrazine  | 0.985             | 4.0245                       |
| MMH        | 1.025             | 3.3296                       |
| UDMH       | 0.540             | 1.6895                       |

Data source: [309]

In a study of the rate of oxidation of MMH or UDMH as affected by pH and  $\text{Cu}^{2+}$  concentration, the authors concluded that for most real-life spill surface water conditions, neither UDMH nor MMH would persist for longer than a day or two in the absence of highly acidic conditions [310]. The kinetics of oxidation of MMH by dissolved oxygen in water has been measured at various acidities as a function of catalyst (cupric ion) concentration. In dilute solutions the oxidation occurs through a cupric ion catalyzed process as well as by an uncatalyzed step. Some formaldehyde was also detected during MMH autoxidation.

Glassware used for an environmental degradation study of hydrazines in seawater, pond water, and pure water was carefully washed with 50% nitric acid prior to use. This rigorous cleaning was necessary to achieve reproducible results [311, 312]. Before the environmental degradation tests in soil were started, it was necessary to know the rate of degradation in surface waters without the effect of soil. In the absence of soil or catalysts, aqueous half-lives were ~13 days for MMH and 6–13 days for UDMH. Additional half-life data are summarized in Table 33.

**Table 33:** Half-life of methylhydrazine in natural waters.

| Fuel            | Initial concentration, mM | Pond water, days | Sea water, days |
|-----------------|---------------------------|------------------|-----------------|
| MMH             | 19.0                      | $13.1 \pm 1.1$   | $13.1 \pm 2.2$  |
| MMH             | 9.5                       | $18.0 \pm 2.3$   | $24.1 \pm 8.8$  |
| For comparison: |                           |                  |                 |
| UDMH            | 13.1                      | $22.2 \pm 6.9$   | $12.6 \pm 2.8$  |
| UDMH            | 6.5                       | $16.3 \pm 6.9$   | $12.6 \pm 1.1$  |
| UDMH            | 0.9                       | $7.3 \pm 1.0$    | —               |
| Hydrazine       | 1.8                       | $8.3 \pm 0.6$    | —               |

Data source: [311, 312]

For a wastewater aeration basin with a common hydraulic detention time of 9 h, the efficiency of organics removal was seriously hampered when the MMH or UDMH concentration exceeded 5 or 8 mg/L, respectively [313]. As far as organics removal is concerned, the “no effect level” would be approximately 2mg MMH or UDMH/L. However, even at this low level, nitrogen speciation (ammonia conversion to nitrate) was severely impeded. Inhibition of nitrification occurred at concentrations above 0.5mg MMH/L and above 1mg/L for the other fuels. Both MMH and UDMH were still detectable under the same conditions, and their efficiency of removal was only 89 and 96%, respectively.

The degradation of MMH by dissolved oxygen in water was carried out in a variable volume and airtight reactor, which made it possible to continuously determine the oxygen and MMH (0–300 ppm) content by successive samplings, while remaining monophasic all-liquid [314]. The oxidation of the MMH was then studied in a strictly gaseous medium by means of an experimental setup designed to ensure a good vacuum resistance (10 Pa) up to a temperature of 473 K (200 °C). This installation made it possible to scan all the O<sub>2</sub>/MMH ratios, to follow the evolution of the gas mixture with the progress of the reaction, and to carry out an overall analysis of the reaction medium by GC. The identification of the different products was carried out using GC-MS and cross-checking their retention time. The results obtained in normal gaseous atmospheres showed that the O<sub>2</sub>/MMH system is a system of complex reaction chains owing to the high probability of interactions between free

molecules such as hydrazones and tautomeric forms of methyldiazene. The kinetic and thermodynamic parameters of activation energy have been determined and a reaction sequence was proposed.

The kinetics of the oxidation of MMH by dioxygen was studied in reducing medium (excess of MMH) as a function of the concentrations ( $[O_2] \leq 4 \times 10^{-4}$  mol/L,  $[MMH] \leq 6 \times 10^{-3}$  mol/L), pH (11 to 14), and temperature (298 to 318 K = 25 to 45 °C) [315]. The measurements were carried out in strictly monophasic medium in an isothermal, isobaric reactor with variable volume. The reaction is first order with respect to each of the reactants. The reaction orders and the stoichiometry were independent of the pH and within the range studied, and the variation of the rate constant was insignificant to be interpreted in terms of acid–base catalysis. The major product of the reaction was methanol. No compounds with chromophoric groups were observed. The isobaric isothermal reactor consists of a compensating piston that allows reagent injection and sample withdrawal without the appearance of a gaseous phase [316, 317].

#### 4.6.1.7 Reactions of MMH with Ozone

Ozone ( $O_3$ ) constitutes a more active form of oxygen and releases atomic oxygen during its decomposition. Ozonization is a clean method of decontamination of hydrazine(s) in rinse waters from propulsion systems. A parametric study of the ozonization of hydrazine, MMH, and UDMH investigated the effects of reactant concentration, pH, UV catalysis, and ultrasonic agitation on the rates of hydrazine(s) destruction [318, 319]. Two types of gas-sparging constant-volume stirred reactors were used, a 35-L UV reactor and a 5-L reactor with an ultrasonic agitator. The gas flow rate was typically 30 scfm. Ozonized air contained approximately 1% by weight ozone. Higher ozone concentrations (2% by weight) were possible with ozonized dry oxygen. The reaction rate increased with increasing pH. Ultraviolet light acted as a catalyst and decreased the half-life further. UV had some beneficial effect with MMH and UDMH. Kinetic analysis of the MMH concentrations showed that the data fit a zeroth-order and UDMH data fit a half-order relationship. Autodecomposition of dissolved ozone also followed a zeroth-order relationship. Even with very high initial hydrazine concentrations, the rate of hydrazine destruction followed a zeroth-order relationship after 15 min of bubbling ozone through the solution. The half-lives of the hydrazines in contact with ozone are summarized in Table 34.

In addition to the rate of hydrazine(s) disappearance, reaction products (nitrate, organics) were analyzed using spectrophotometric and GC-MS methods. Residual nitrate is undesirable and would make it more difficult to discharge the reactor effluents to surface waters. In the case of MMH ozonization, methanol was a by-product (predominantly at low-pH operation) that had secondary ozone requirements beyond the point where all MMH had disappeared. Methanol becomes oxidized/ozonized much more slowly than MMH. Again, measurable residual methanol

**Table 34:** Reaction of ozone with hydrazine, methylhydrazine (MMH), and unsymmetrical dimethylhydrazine (UDMH).

| Reaction conditions |                          | Half-life time, minutes |                               |                        |

Data source: [318]

concentrations would make it difficult to find a location where the ozonized MMH waste can be safely discharged to surface waters. In addition to methanol, there were four unidentified GC peaks. In the case of UDMH, the main reaction by-products were *N*-nitrosodimethylamine (NDMA) and dimethylformamide, in addition to 13 other unidentified peaks. UV spectra indicated formaldehyde dimethylhydrazone and tetramethyltetrazene.

The oxidation of MMH and UDMH by ozone is not complete but leads to organic products that may also be toxic [320–322]. Ozonization alone is not completely effective in decontaminating MMH- or UDMH-contaminated wastewater.

Reaction rates of hydrazines with ozone would be similar to reaction rates with atomic oxygen and hydroxyl free radicals, which are expected if MMH vapors are released into the atmosphere and exposed to direct sunlight. The reaction of atomic oxygen with MMH may excite fluorescent emissions at characteristic wavelengths within the UV and visible range.

The gas-phase reaction of MMH with ozone was investigated in a flow tube at atmospheric pressure and a temperature of  $295 \pm 2$  K using  $N_2/O_2$  mixtures (3–30 vol-%  $O_2$ ) as the carrier gas [323]. Proton transfer reaction-mass spectrometry and long-path FTIR spectroscopy served as the main diagnostic techniques. The kinetics of the reaction were investigated using a relative rate technique yielding:

$$k_{\text{MMH} + \text{O}_3} = (4.3 \pm 1.0) \times 10^{-15} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

Methyldiazene was identified as the main intermediate product in this reaction system. The reactivity of methyldiazene toward ozone was estimated relative to the reac-

tion of MMH with ozone, resulting in:

$$k_{\text{HN=NCH}_3 + \text{O}_3} = (2.7 \pm 1.6) \times 10^{-15} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

Increasing OH radical yields with increasing MMH conversion have been observed, pointing to the importance of secondary processes for OH radical generation. The results of this study did not support the mechanism of OH radical formation from the reaction of MMH with ozone as proposed in the literature, a reaction that was known to take place between hydrazine  $\text{N}_2\text{H}_4$  and ozone.

#### 4.6.1.8 Reactions of MMH with Nitrogen Dioxide

The hypergolic reaction of MMH with dinitrogen tetroxide is the main reason why that much MMH has been produced in the first place. Applications of the NTO/MMH propellant combination in rocket engines will be presented in a future *Encyclopedia of Hypergolic Bipropellant Combinations*.

Slow reactions of MMH with  $\text{NO}_2$  in the gas phase might occur in the vicinity of propellant storage areas where propellant has leaked, or in a rocket combustion chamber after the engine has shut down and the dribble volume slowly empties itself without a combustion reaction. These reactions also have to be anticipated if a bipropellant engine is fired for a very, very short pulse and fails to ignite.

The slow reaction of  $\text{N}_2\text{O}_4$  and MMH vapor diluted in high-pressure helium (15 MPa = 250 psia) was studied in 1989, but unfortunately the lessons learned were not applied to the design of the propellant pressurization system of the Mars Observer space probe, where oxidizer and fuel shared a common pressurant tank, leading to the loss of the spacecraft in 1993 [324]. In this test, helium saturated with  $\text{NO}_2$  ( $\text{N}_2\text{O}_4$ ) and helium saturated with MMH at 293 K (70 °F) were rapidly injected into an instrumented test section with 65 mL (4 in<sup>3</sup>) internal volume consisting of CRES-304 tubing with an outer diameter (O.D.) of 9.5 mm (3/8-in). There were no observable pressure or temperature spikes as a result of the mixing. The vapor mixing caused a number of complex reactions, resulting in accumulation of solid, yellow residues. Gas-phase analysis showed the presence of nitrous oxide, methyl nitrite, methyl nitrate, methanol, dimethyldiazene, methyl formate, acetonitrile, traces of diazomethane, 2-propanol (cleaning solvent contaminant), and its reaction products acetone and 2-propyl nitrite. Analysis of rinse water showed MMH nitrate and surprisingly high levels of sulfate and phosphate as contaminants (probable residues from aqueous industrial cleaners). Additional tests were performed with hydrazine instead of MMH (because some dual-mode systems, e.g., CASSINI, NEAR, Mars Climate Orbiter, use hydrazine as the fuel and may share a pressurant tank). These tests did not result in explosions.

In the slow, vapor phase reaction of  $\text{N}_2\text{H}_4$  with  $\text{NO}_2$  an intermediate nitrosamine  $\text{ONNH}_2$  has been postulated, but in the case of hydrazine itself, nitrosamine could not be detected because it is very unstable. However, nitrosamines are stable if

hydrogen in hydrazine is substituted by one or two methyl groups. The reaction of MMH with NTO leads to methylamine, dimethylamine, *N*-nitrosomethylamine, *N*-methylformamide, methanol, MMHN, water, nitric oxide, nitrous oxide, nitrogen, and carbon dioxide [325].

Residues from NTO/MMH engines firing in vacuum chambers at steady-state or pulse mode were collected from cryopanel and analyzed [326, 327]. IR spectra of the residues matched those of MMHN (see Section 5.2.1). When introducing gaseous NO<sub>2</sub> into a vacuum chamber containing liquid or solid N<sub>2</sub>H<sub>4</sub>, MMH, Aerozine-50, or UDMH at pressures below 13.3 kPa (100 mm of Hg) and a temperature of 262 K (−11 °C), a flameless reaction took place with a noticeable deposition of a viscous condensed phase. Oily residues thus obtained were identified by IR analyses as nitrate salts of the fuel. The buildup of non-volatile, partially combusted products occurred under these low-pressure conditions where only a flameless reaction takes place, and would lead to pressure spikes next time the engine ignites.

A detailed kinetic model of the gas-phase hypergolic ignition of NTO–MMH mixtures below 298 K and their combustion above 1000 K consisted of 403 reactions among 82 species [328]. The predictions of this mechanism were compared with theoretical data available in the literature and the agreement between theory and predictions was good. Important reactions for ignition at low initial temperature and pressure have been identified through sensitivity analyses. Two competing pathways can explain hypergolic ignition at low temperature. The formation of molecular preignition products was shown to promote the ignition. This conclusion was unexpected, as the formation of these products was generally considered to inhibit the ignition by reactant consumption. Some reactions are important both for low-temperature ignition and combustion, whereas others are important either for ignition only or combustion only.

Previous studies showed the formation of products, appearing as a white-yellow fog, when NO<sub>2</sub>/N<sub>2</sub>O<sub>4</sub> and MMH vapor come into contact without ignition. This product formation is visible to the naked eye and appears almost instantaneously. Based on UV spectrophotometry measurements, this formation seems to be complete in less than 100 ms. This product formation seems to be unavoidable and is observed even if the two gases are both highly diluted (up to 97 mol-% He). High-speed imagery revealed what happens when a jet of NTO is introduced into a spherical metallic bomb that contains MMH vapor. The formation of product species occurred on a time scale of tens of milliseconds. Kinetic models derived for the NO<sub>2</sub>/N<sub>2</sub>O<sub>4</sub> and MMH vapor reaction were confirmed by measuring the ignition boundaries of NO<sub>2</sub>/N<sub>2</sub>O<sub>4</sub> and MMH vapor as a function of helium dilution, mixture ratio, and pressure at room temperature [329].

Reactive collisions between CH<sub>3</sub>NNH<sub>2</sub> + NO<sub>2</sub> and CH<sub>3</sub>NHNH + NO<sub>2</sub> vapors were simulated via direct molecular dynamics simulations [330]. A number of different H-atom abstraction paths were observed, with four isomeric (CH<sub>4</sub>N<sub>2</sub>) products being formed: CH<sub>3</sub>NNH, CH<sub>3</sub>NHN, H<sub>2</sub>CNNH<sub>2</sub>, and CH<sub>2</sub>NHNH. All abstractions were

barrierless, including those from the methyl group. The results suggested that finite rate chemical kinetics mechanisms for MMH/NTO and MMH/red fuming nitric acid (RFNA) systems should include steps for the production and decomposition of  $\text{CH}_3\text{NHNH}$ ,  $\text{H}_2\text{CNNH}_2$ ,  $\text{CH}_2\text{NHNH}$ , and  $\text{CH}_3\text{NHN}$  in addition to those for  $\text{CH}_3\text{NNH}_2$  and  $\text{CH}_3\text{NNH}$  [331]. Five transition states connecting  $\text{CH}_3\text{NHNH}_2 + \text{NO}_2$  complexes were identified. Transition states that connect  $\text{MMH} + \text{HNO}_2$  complexes to each other via H atom exchange and/or hindered internal rotation were also identified. The high point in the minimum energy path from the  $\text{CH}_3\text{NHNH}_2 + \text{NO}_2$  reactant asymptote to the manifold of nitrous acid (HONO)-containing product states was a transition state 36 kJ/mol (8.6 kcal/mol) above the reactant asymptote. From a kinetics standpoint, this value was considerably higher than the 24.7 kJ/mol (5.9 kcal/mol) value that was estimated for it based on theoretical results for H atom abstraction from  $\text{NH}_3$  by  $\text{NO}_2$ . The practical, real-world value of such esoteric calculations remains to be demonstrated.

An examination of the early reaction chemistry of hypergolic reactions between MMH and  $\text{NO}_2$  vapor at room temperature and 1 atm  $\text{N}_2$  used a gold-coated chamber reactor and a FTIR spectrometer [332]. The IR-active species identified in the early reactions include HONO, methylhydrazinium nitrite ( $\text{MMH} \cdot \text{HONO}$ ), methyl diazene ( $\text{CH}_3\text{N}=\text{NH}$ ), methyl nitrate ( $\text{CH}_3\text{ONO}_2$ ), methyl nitrite ( $\text{CH}_3\text{ONO}$ ), nitromethane ( $\text{CH}_3\text{NO}_2$ ), methyl azide ( $\text{CH}_3\text{N}_3$ ),  $\text{H}_2\text{O}$ ,  $\text{N}_2\text{O}$ , and  $\text{NO}$ . Based on quantum mechanical studies, it was proposed that the oxidation of MMH in an atmosphere of  $\text{NO}_2$  occurs via two mechanisms: **(1)** sequential H-abstraction and HONO formation, and **(2)** reaction of MMH with asymmetric  $\text{ONONO}_2$ , leading to formation of methyl nitrate. These mechanisms successfully explain all intermediates observed experimentally. It was theorized that the formation of asymmetric  $\text{ONONO}_2$  is assisted by an aerosol formed by HONO and MMH that provides a large surface area for  $\text{ONONO}_2$  to condense, leading to the generation of methyl nitrate. It was proposed that the overall pre-ignition process involves both gas-phase and aerosol-phase reactions. Quantum mechanics calculations were supposed to expose the possible mechanisms by which these products were formed. These studies proposed that the intermediates found within the condensate play a fundamental role in the ignition event. Regarding  $\text{MMH}-\text{NO}_2$  liquid-phase reactions, it was not possible to find rate constants or activation energies in open literature. For the  $\text{MMH} + \text{NO}_2 \rightarrow \text{HONO} + \text{methylhydrazyl}$  radical reaction, Catoire et al. estimated an activation energy value of 24.7 kJ/mol (5.9 kcal/mol) based on comparisons with reactions between  $\text{NH}_3$  and  $\text{NO}_2$ . As both reactions involve hydrogen atom abstraction, the comparison was thought to be valid.

In addition to ignition delay measurements and high-speed camera recordings of NTO/MMH and RFNA/MMH droplet reactions, time-resolved UV/vis emission spectra of NTO/MMH and RFNA/MMH ignition flames were recorded with a streak camera coupled with a spectrometer for species emitting wavelengths from 250 to 950 nm

within a point of interest above the reaction zone measuring 1 mm in diameter [333]. NTO/MMH consistently produced brighter flames than RFNA/MMH and as such generally generated higher intensity signals for a given spectrometer setting. Both propellant combinations revealed conclusive evidence for OH and NH radicals and probable evidence of CN and/or CH radicals. In most tests OH yielded the highest intensity signals with both RFNA and NTO. NTO/MMH revealed greater NH intensity than RFNA/MMH.

#### 4.6.1.9 Reaction Kinetics of N<sub>2</sub>O<sub>4</sub>/MMH Reactions

A substantial amount of information is available on liquid–liquid interaction of N<sub>2</sub>O<sub>4</sub> and MMH, leading to hypergolic ignition and use of this propellant combination in thousands of rocket engines. Very rarely does the need arise to look at the vapor-phase reaction of N<sub>2</sub>O<sub>4</sub> and MMH under conditions that do not immediately lead to ignition.

Potential problem areas in the design of storable bipropellant systems are the pressurization systems if they share a pressurant tank. Under ordinary conditions, propellant vapors would not back up into the helium as they are separated by a series of enable valves, check valves, and pressure regulators. During long interplanetary cruise phases, while the system is idle, it is possible for propellant vapors to permeate through the Teflon seat material of the valves and condense on the other side if that is the coldest part of the system. The reaction of N<sub>2</sub>O<sub>4</sub> and MMH diluted in high-pressure helium (15 MPa = 250 psia) was studied already in 1989, a study that would later help to explain the loss of the Mars Observer space probe in 1993 [334]. In this test, helium saturated with N<sub>2</sub>O<sub>4</sub> and helium saturated with MMH were rapidly injected into an instrumented test section with 65 m (4 in<sup>3</sup>) volume consisting of CRES-304 tubing with an O.D. of 9.5 mm (3/8-in). There were no observable pressure or temperature spikes as a result of the mixing.

#### 4.6.1.10 Reaction of MMH with Nitrous Acid Nitrosation of Methylhydrazines

Although it is not possible to isolate the nitrosohydrazine as an intermediate in the NO<sub>2</sub>–hydrazine reaction, the nitroso derivatives of MMH and UDMH are stable enough to be isolated as intermediates. The nitrosation of MMH and UDMH proceeds through their conjugate acids and can be achieved with nitrous acid, nitrosonium ion, or nitrosyl halides as an electrophilic agent. For MMH, the product distribution shows that sizeable proportions of both possible protonated methylhydrazines must exist in solution. In the presence of an excess of nitrous acid, a secondary reaction can lead to the destruction of nitrosomethylhydrazine. The possible involvement of a dinitroso intermediate cannot be excluded. Reaction products are methanol, dinitrogen, and dinitrogen oxide:

#### 4.6.1.11 Mechanism and Kinetics of the Oxidation of MMH in Solution

The products of monoalkyl hydrazine oxidation depend on the type of oxidant used. Oxidation by air or oxygen or nitrogen dioxide was already discussed above. For other types of oxidizers, for example, when MMH is oxidized by hexacyanoferrate(III) or periodate in alkaline solution, it is converted to methane. Other monoalkylhydrazines are likewise converted to the corresponding alkanes. Surprisingly, oxidation of alkylhydrazines by iodine in non-aqueous or aqueous media gives alkyl iodides in good yields, better than 70% [335]. A little alkane is usually formed as a by-product by reduction of the alkyl iodide. In aqueous media, some alkanols are formed as well.

When studying the stoichiometry and kinetics of MMH oxidation by manganese(III), it was found that Mn(III) oxidizes MMH according to the following equation without formation of nitrogen [336]:

When using cerium(IV) in acid solution in place of manganese(III), a rate expression:

$$-d[\text{Ce(IV)}]/dt = K_H[\text{Ce(IV)}][\text{CH}_3\text{N}_2\text{H}_4^+]$$

was found that was identical in form to that found for Mn(III), but construed a different mechanism because nitrogen gas was evolved [337]. The  $k_H$  value was found to be pH dependent. When the molar ratio MMH:Ce(IV) was higher than 4, the molar ratio of  $\text{N}_2$  evolved to Ce(IV) consumed was 1:4. The observed stoichiometry can be explained by either one of the following two equations:

Radical cations of MMH and UDMH were generated by reaction of MMH or UDMH with cerium(IV) in sulfuric acid solutions in a fast-flow mixing chamber, and the electron spin resonance (ESR) spectra of these short-lived intermediates were recorded and experimental nitrogen and proton coupling constants determined [338]. Molecular orbital calculations for molecules were performed and the implications for reaction mechanisms for the oxidation of the hydrazines were explained.

#### 4.6.1.12 Electro-Oxidation of MMH in Solution

The electrochemical oxidation of hydrazine or MMH forms the basis of a rocket propellant vapor-sensing device used to monitor the space shuttle launch pad [339]. In alkaline electrolytes, such as 23% KOH, both hydrazine and MMH were electro-oxidized on gold electrodes at all potentials. It was possible to minimize interference by maintaining the sensing electrode potential at 1.1 V, where CO and NO are unreactive and where the signal caused by  $\text{NO}_2$  is weak. Of course, in a flow-through instrument, not all the contaminants are oxidized at high flow rates, whereas at low flow rates,

all the hydrazines are oxidized. If one plots the number  $z$  of electrons consumed per unit reaction as a function of gas flow rate, the curve intersects the ordinate at  $z = 4$  for flow rates approaching zero. This can be explained if one assumes that the overall electrochemical oxidation of hydrazine at 1.1 V on gold proceeds as:

and likewise for MMH:

In analogy to the studies on hydrazine, the electro-oxidation of MMH, UDMH, and SDMH at a platinum electrode has been investigated using chronopotentiometry, coulometry, and product analysis [340]. Controlled potential coulometric oxidation of the MMH experiments were performed in a gas-tight cell designed for gas volume measurements and product analysis. Because of the strong dependence on such factors as the nature of the electrode surface and spontaneous catalytic decomposition of the methylhydrazines at the electrode surface, the reproducibility of the data was only fair. The results of this study bear certain significance for the attempted polarographic analysis of these compounds. The results showed that MMH is oxidized in a four-electron (gross) reaction to nitrogen and methanol. The measurements were done with an experimental setup that can collect, measure, and analyze gaseous electrolysis products of alkylhydrazines [341].

Three different methods were used to study the anodic oxidation of MMH and UDMH: cyclic voltammetry, controlled potential electrolysis, and potentiostatic step measurements [342]. The oxidation was achieved on smooth platinum electrodes in 1 M sulfuric acid or 2 M perchloric acid. The oxidation of MMH liberates four electrons according to:

Methyldiazene (= methyldiimine)  $\text{CH}_3\text{N}=\text{NH}$  is a very likely intermediate oxidation product that had already been postulated by previous investigators.

The electro-oxidation of MMH in alkaline solutions has been studied on a mercury electrode [343]. Polarography and cyclic voltammetry were used to determine the parameters of the oxidation process. A mechanism that fits the experimental results was proposed in which the rate-determining step consists of the reaction of an adsorbed OH radical with an MMH molecule. The electro-oxidation of MMH on a gold electrode in  $\text{H}_2\text{SO}_4$  has been studied by linear sweep, steady-state, and quasi steady-state methods [344]. The oxidation process mechanism involves two fast de-electronation reactions and the rate-determining step is an activated desorption step. The following reaction has been proposed:

The rate-determining step involves a diazenium cation:

Although the overall reaction yields four electrons, the kinetics are determined by a one-electron step. The shape of the current-potential curve was dependent on the anion present (sulfate or perchlorate). This may be caused by the different oxygen density on the anode, an effect that may be superimposed on the true electrochemical MMH oxidation. The peak in the polarogram may be caused by both modes of oxidation.

#### 4.6.1.13 Complex-Forming Reactions of Alkylhydrazines

Just like its parent molecule, hydrazine, MMH can serve as a bidentate or unidentate ligand in complexes with transition metal cations [345]. Some of such complexes may be found among the corrosion products of contaminated MMH that was stored in metal tanks. The aqueous solution reactions between cobalt(II) chloride and MMH or UDMH lead only to precipitation of cobalt (II) hydroxide owing to the greater basic strengths of these ligands. The addition of MMH to a solution of cobalt(II)chloride hexahydrate in alcohol gave a pale violet precipitate of  $\text{CoCl}_2 \cdot 2\text{MMH}$  [346]. In the absence of a solvent, a compound  $\text{CoCl}_2 \cdot 6\text{MMH}$  is obtained, which is unstable in moist air and insoluble in MMH. In UDMH,  $\text{CoCl}_2$  gives an intensely blue solution, from which deep blue tetrahedral  $\text{CoCl}_2 \cdot 2\text{UDMH}$  crystals can be crystallized. This complex most likely has a tetrahedral structure with UDMH serving as a unidentate ligand. An octahedral complex could not be obtained, which may be due to steric hindrance of the methyl group(s). In the cationic complex  $[\text{Co}(\text{MeNHNH}_2)_6]\text{Cl}_2$ , the ligands are unidentate but in  $\text{CoCl}_2 \cdot (\text{MeNHNH}_2)_2$  the crystals are polymeric, with bridging and bidentate hydrazines. This pale violet precipitate of  $\text{CoCl}_2 \cdot (\text{MeNHNH}_2)_2$ , like the hydrazine analog, is insoluble in solvents with which it does not react. Similar complexes are formed with cobalt salts where the anion is bromide, iodide or isothiocyanate instead of chloride and two or six ligands are tied to the central cobalt atom [347].

The IR spectra and magnetic properties of eight complexes of nickel(II) chloride with hydrazine, MMH, or UDMH were measured [348]. In complex structures similar to the hydrazine-bridged complex  $\text{Ni}(\text{N}_2\text{H}_4)_2\text{Cl}_2$ , nickel(II) chloride forms  $\text{Ni}(\text{N}_2\text{H}_4)_3\text{Cl}_2$  in which the nickel atom is surrounded by six nitrogen atoms as nearest neighbors. In a similar vein, MMH forms  $\text{Ni}(\text{MeNHNH}_2)_2\text{Cl}_2$  and  $\text{Ni}(\text{MeNHNH}_2)_6\text{Cl}_2$  whereas 1,1-dimethylhydrazine forms  $\text{NiCl}_2 \cdot 4\text{UDMH}$ ,  $\text{NiCl}_2 \cdot 2\text{UDMH}$ , and  $\text{NiCl}_2 \cdot \text{UDMH}$ . The spectra and magnetic moments of all the complexes were consistent with octahedral (or tetragonal) stereochemistry.

A full normal coordinate analysis has been carried out on MMH, *N*-deuterated MMH, and the bidentate nickel complex  $\text{NiCl}_2 \cdot (\text{NH}_2\text{NHCH}_3)_2$  [349]. The  $C_{3v}$  symmetry of the methyl group is lost in MMH. Nevertheless, the concept of specific methyl group modes is still valuable. The N—N stretching mode is relatively pure, enabling it to be used as a criterion of coordination in complexes with transition metals. Interest-

ing changes were observed for the wagging and twisting modes of the  $\text{NH}_2$  group on coordination in a complex.

Methylhydrazine and methylhydrazinium chloride complexes of copper in various oxidation states (1+, 2+) have been prepared and characterized by elemental analyses and magnetic data [350]. The thermal decomposition of these complexes was studied by simultaneous DTA, TGA, and DTG. The complex  $\text{Cu(II)Cl}_2 \cdot (\text{NH}_3\text{NHCH}_3\text{Cl})$  decomposed on heating with reduction to  $\text{Cu(I)Cl}$ . Significantly, the mixed valence complex  $\text{Cu}_3(\text{2I, II})\text{Cl}_6(\text{NH}_3\text{NHCH}_3)_2$  on heating disproportionated as follows:  $3\text{Cu} \rightarrow 2\text{Cu(I)} + \text{Cu(II)}$ .

#### 4.6.1.14 Reaction of MMH with Carbon Dioxide

Methylhydrazine absorbs  $\text{CO}_2$  rapidly from the air, with a more than eleven-fold increase in  $\text{CO}_2$  content during the first 10 min. of an open-air experiment with 20 mL MMH in a 50-mL beaker [351]. After 60 min., the  $\text{CO}_2$  concentration had increased to 1600 ppm. Typical propellant samples taken from drums and flight systems contained 25 to 224 ppm  $\text{CO}_2$ . Carbon dioxide in MMH exists in the form of methylcarbamic acid, which forms salts and complexes with many metals. Methylhydrazine and  $\text{CO}_2$  give the thermally unstable salt  $[\text{CH}_3\text{NHNH}^+\text{H}_3]=[\text{CH}_3\text{NHNHCOO}^-]$ , which can react with  $[\text{Cr}(\text{H}_2\text{O})_4\text{Cl}_2]\text{Cl} \cdot 2\text{H}_2\text{O}$  in ethanol to give  $[\text{Cr}^{\text{III}}(\text{H}_3\text{CNHNHCOO})_3] \cdot \text{H}_2\text{O}$  [352].

The stability of MMH is greatly affected by the presence of impurities. Six new metal complexes containing methylhydrazinecarboxylate and 1,1-dimethylhydrazinecarboxylate were prepared and the effects of these complexes on the homogeneous decomposition rates of the propellants were investigated. It was concluded that the  $\text{Mn(II)}$  methylhydrazinecarboxylate complex has a greater effect than either the  $\text{Cr(III)}$  or the  $\text{Ni(II)}$  complexes on the stability of MMH [353]. It was concluded that impurity profiles and stability are greatly affected by the manufacturing method.

Methylhydrazine, hydrazine, or ethylenediamine react readily and reversibly with carbon dioxide to form methylhydrazinium carboxylate, hydrazinium carboxylate, or ammonium carbamate adducts, respectively [354]. These adducts act as low-molecular-weight gelators, which self-assemble and in doing so trap unreacted hydrazines or diamine. The properties and molecular structures of the gels were investigated by means of elemental analysis, DSC-TGA, heteronuclear NMR ( $^1\text{H}$ ,  $^{15}\text{N}$ , and  $^{13}\text{C}$ ), diffusion-ordered NMR spectroscopy, and cryo-immobilized high-resolution scanning electron microscopy (SEM), providing a pictorial representation of the bulk gel structures on the molecular level.

#### 4.6.2 Reactions of MMH with Organic Compounds

Reactions of acyl chlorides and anhydrides with MMH lead to methylhydrazides of the carbonic acids. Reactions of MMH with carbonyl compounds are sometimes per-

formed as an intermediate step in the synthesis of heterocycles. Reaction of MMH or hydrazine with formaldehyde and methylamine led to cyclic 1,2,4- or 1,3,5-triazine derivatives.

Before getting too involved in the complex area of hydrazine reactions with carbonyl compounds, it may help to clarify the nomenclature here:

|                 |           |
|-----------------|-----------|
| $R-CH=N-NH_2$   | aldazone  |
| $R-CH=N-N=CH-R$ | aldazine  |
| $R_2C=N-NH_2$   | hydrazone |
| $R_2C=N-N=CR_2$ | ketazine  |

## 4.7 Analysis of MMH

The analysis of MMH is of importance in the production, quality control, application, occupational hygiene, and environmental control of this propellant. For the most part, the analysis methods will have to be quantitative. Many excellent monographs and survey articles appeared several decades ago, which makes a separate chapter on hydrazine(s) analysis almost unnecessary. A useful reference on this subject is a book on the determination of hydrazino-hydrazide groups [355]. The same author also published several chapters on hydrazines in a book on the analysis of rocket propellants [356] and did a thesis on the analysis of hydrazine compounds [357].

Most of the methods of analysis of MMH can also be used for the determination of hydrazine and/or UDMH. It is unavoidable that several of the references in this section will appear more than once. In some instances, if two or more hydrazines are present, it may be difficult to separate them from each other to obtain individual quantity assessment.

Most analytical procedures are performed in the convenience of a chemistry laboratory, but in the case of rocket propellants, it will also be necessary to have portable instruments that operate under rugged conditions at launch sites, in the battle field, or at sites of suspected environmental pollution.

### 4.7.1 Qualitative Analysis of MMH

Qualitative analyses of MMH and other hydrazines give only a “yes” or “no” answer and alert the analyst to a potential source of pollution or hazardous conditions for propellant handling personnel. In most cases, a surprise positive qualitative test will require a follow-up using a calibrated quantitative analysis method.

### 4.7.2 Assay and Specification Analysis of MMH

Propellant that has been off-loaded from reusable spacecraft such as the Space Shuttle has to be discarded or recycled, regenerated, and re-qualified before it can be loaded

into a spacecraft or launch vehicle again. A NASA specification describes the recommended handling, sampling, and analysis methods for hydrazine-based fuels such that it can be decided if the material should be reprocessed, returned to the manufacturer for reprocessing, or discarded [358]. A bench-top distillation unit was able to reduce NVR contamination levels in off-loaded MMH of 12 to 25 mg/L to a level of 0.1 to 0.2 mg/L so it would again meet military (MIL) and NASA specs [72]. This testing was done in preparation for the installation of a larger distillation unit.

#### 4.7.3 Gas Chromatographic Analysis Methods for MMH

Gas chromatography is the most versatile method for both quantitative and qualitative (quality control) analysis of alkylhydrazines. Most alkylhydrazines are of sufficient volatility to allow separation from each other and from other constituents by GC. However, the tendency of most alkylhydrazines to undergo thermal or catalytic decomposition severely limits the operating temperatures and the choice of materials in the GC system. Gas chromatography is also used for the analysis of gaseous decomposition products of alkylhydrazines. Most of the GC applications use a liquid stationary phase, and the exact abbreviation would be GLC. Suffice it here to say that GC and GLC are intended to serve as abbreviations for the same analytical methods.

Methylhydrazine, water, and hydrazine were nicely separated at 383 K on a column measuring 1/4-in. in diameter  $\times$  6 ft long filled with 10% Dowfax 9N9 on 60–80-mesh Teflon-6 [359, 360]. The fractogram also revealed traces of nitrogen and ammonia. For calibration purposes, response factors for water in hydrazine or MMH were determined by analyzing calibration mixtures of known composition. The reciprocal response ratio for water in MMH remained constant (1.15–1.20) for mixtures with 16–72% H<sub>2</sub>O in MMH. The column did not give satisfactory separation of UDMH from water in any of these mixtures. The column showed no loss of separating power after 200 injections. The addition of 1% sodium hydroxide to the stationary phase did not improve hydrazine separation, and better results were achieved in columns without NaOH.

##### 4.7.3.1 Gas Chromatographic Analysis of Impurities in MMH

Propellant-grade MMH analyzed on a 12-ft  $\times$  1/4-in. column packed with 4% Quadrol on Chromosorb T showed ammonia, AM, methylamine, water, and hydrazine, plus six unidentified peaks as contaminants [206]. Some of the unknowns could possibly be methanol, formaldehyde methylhydrazone, and cyanogen derivatives. Several of these unknown peaks increased in size if the MMH was analyzed after heating it to 473 K for 21 h.

In a similar study, MMH was analyzed on a 6-ft  $\times$  0.125-in. column packed with 100–120-mesh Chromosorb 103 [230]. Propellant-grade MMH samples typically contained 100 ppm methanol, 50 ppm ethane, 50 ppm AM, 50 ppm SDMH, and 50 ppm UDMH. Most of the contaminants were thought to be the result of air oxidation.

The analysis methods specified in earlier Military Specifications for hydrazines and hydrazine mixtures used packed GC columns, which usually resulted in broad, poorly resolved peaks. Increased component information and analysis speed can be achieved with capillary gas chromatography. Two capillary column methods of hydrazine analyses were developed at NASA WSTF and shared with round-robin participants. A round-robin analysis campaign was conducted with seven participating laboratories to gather multiple laboratory precision data for analysis of hydrazines using capillary GC [361]. Acceptable data were received from six of the laboratories. The fuels were analyzed for water, aniline, and other volatile carbonaceous material such as isopropyl alcohol. Statistical analysis of the results suggested that increased analyst experience with these capillary GC methods should significantly reduce inter-laboratory differences in the future.

Only a few methods that combine GC with means of identifying the eluting peaks other than by retention volume give completely satisfactory results. GC-MS gives the  $m/e$  of the fragments of the eluting hydrazine and alkylhydrazines, but in the presence of organic contaminants, many CH compounds have fragment peaks at the same  $m/e$  ratios as NH compounds. GC-IR has attempted to avoid this problem by using IR absorption lines specifically for hydrazines [362]. The effluent from the GC was passed through a gold-plated optical waveguide with multiple reflections where IR absorption took place. The spectra were processed in an FTIR computer for compound identification.

The stability of MMH is greatly affected by the presence of impurities. Most organic impurities are present in the propellant from manufacture. In order to assess the likely range of impurities a review of manufacturing methods for propellant hydrazines was undertaken. This was followed by a stability assessment and impurity survey (using GC-MS) on samples of MMH and UDMH from four different sources [353]. It was concluded that impurity profiles and stability are greatly affected by the manufacturing method.

#### 4.7.3.2 Gas Chromatography of MMH Following Derivatization

The detection limit for toxic or otherwise troublesome contaminants by GC has generally been improved by several orders of magnitude through the introduction of the Flame Ionization Detector (FID) as the detector at the exit of the GC column. However, the FID is “blind” to hydrazine that combusts only to nitrogen and water. Alkylhydrazines give only a weak signal because they contain very little carbon. The sensitivity for detection of hydrazine(s) by GC-FID can be improved by converting hydrazine(s) to volatile, thermally stable organic derivatives with high carbon (or even some halogen or silicon) content, such as hydrazones or azines. Similarly, the electron capture detector is very sensitive to halogen, and halogen-containing derivatizing agents improve the detection limit dramatically. Derivatives formed between alkylhydrazines and aldehydes or ketones are shown in Table 35.

**Table 35:** Derivatives formed with methylhydrazine (MMH) and unsymmetrical dimethylhydrazine (UDMH).

| Reagent used                | Type of hydrazine analyzed | Derivative formed                                                                  |
|-----------------------------|----------------------------|------------------------------------------------------------------------------------|
| Acetone                     | MMH                        | $\text{CH}_3\text{NH}-\text{N}=\text{C}(\text{CH}_3)_2$                            |
| Acetone                     | UDMH                       | $(\text{CH}_3)_2\text{N}-\text{N}=\text{C}(\text{CH}_3)_2$                         |
| 2,4-Dinitrobenzaldehyde     | MMH                        | $\text{CH}_3\text{NH}-\text{N}=\text{CHC}_6\text{H}_3(\text{NO}_2)_2$              |
| 2,4-Dinitrobenzaldehyde     | UDMH                       | $(\text{CH}_3)_2\text{N}-\text{N}=\text{CHC}_6\text{H}_3(\text{NO}_2)_2$           |
| Furaldehyde                 | UDMH                       |  |
| 2-Nitrobenzaldehyde         | UDMH, daminozide           | $(\text{NO}_2)\text{C}_6\text{H}_4\text{CH}=\text{N}-\text{N}(\text{CH}_3)_2$      |
| Pentane-2,4-dione           | MMH                        |                                                                                    |
| Pentane-2,4-dione           | UDMH                       | $\text{H}_3\text{CCOCH}_2\text{C}(\text{CH}_3)=\text{N}-\text{N}(\text{CH}_3)_2$   |
| Pentafluorobenzoyl chloride | UDMH                       | $(\text{C}_6\text{F}_5\text{CO})_2\text{N}-\text{N}(\text{CH}_3)_2$                |
| Salicylaldehyde             | UDMH                       |  |

One disadvantage of derivatization with 2,4-pentanedione is that this method needs an excess of derivatizing agent for the analysis of mixtures containing UDMH and cannot be used for SDMH in addition to hydrazine or MMH. An alternative derivatization method has been developed using an excess of acetone forming the respective hydrazones of hydrazine, MMH, or UDMH [32]. The hydrazones are then extracted into dichloromethane and separated by GC-FID on a 60-m glass capillary column. In the extract, as little as 0.5 µg/mL UDMH or MMH and 0.2 µg/mL hydrazine could be detected as the hydrazones. The peak area/response factors were determined for synthetic mixtures containing known amounts of the three hydrazines. The recoveries for hydrazine, MMH, and UDMH were 96.2, 98.3, and 97.7% respectively. The turnaround time for this method is very fast, only 20 min for a trained operator. Benzaldehyde and cyclohexanone have been tested as derivatizing agents [363].

**Acetone.** If MMH or UDMH vapors are directly trapped into micro-impingers containing chilled acetone, they are immobilized and derivatized at the same time. The contents of the impingers can be injected without additional sample preparation and the two hydrazones and acetone azine are easily separated by GC using nitrogen-specific thermionic or Thermal Energy Analyzer detectors. This method is much faster

than conventional collection/derivatization methods and is sensitive down to 20 ppb [364, 365]. This procedure used a chilled acetone collection medium that quantitatively trapped the hydrazines and converted them to stable derivatives in a single step. The acetone solution was then assayed directly for the derivatives by using a gas chromatograph with a nitrogen-specific detector. The results obtained from this procedure were in excellent agreement with results obtained using independent analytical techniques, and the overall precision of the method was better than 5% (relative standard deviation) for 90 ppb hydrazine. The minimum detectable concentration was estimated to be approximately 4 ppb. The overall precision was better than 6% for 143 ppb MMH in air. The derivatives formed within minutes in the impinger and were stable in solution for a month. The acetone derivative of MMH was sensitive to light.

A gas chromatographic-mass spectrometric method was developed for analyzing trace levels of MMH in an experimental drug substance [366]. The method used acetone as a dissolving solvent for the drug substance and a derivatizing agent for MMH in the meantime, thus eliminating the need for post-derivatization sample clean-up prior to analysis. The gas chromatographic (direct injection) conditions provided good separation for the acetone-MMH derivative (acetone methylhydrazone) from matrix interference, and mass spectrometric detection (selected ion monitoring mode,  $m/z$  86) enabled detection of 1 part per million (by mass) MMH relative to the drug substance.

**2-Furaldehyde** has been used as a derivatizing agent for all three hydrazines [367, 368]. The method uses sampling tubes containing silica gel or firebrick granules coated with sulfuric acid to analyze for hydrazines in air [369, 370]. After drawing a known volume of workroom air through the tube, the hydrazines as sulfates are extracted from the sorbent with water, liberated with sodium acetate, and reacted with 2-furaldehyde to form azines:

or hydrazones:

The hydrazones and/or azines are extracted using ethyl acetate and quantified by GC after calibration with known standards. A Silicone OV-7 glass column in a gas chromatograph with FID detector gave good separation of the derivatives of all three hydrazines ( $N_2H_4$ , MMH, and UDMH) when the column oven temperature was raised by linear programming.

Firebrick is preferred as an absorbent, because it is geometrically stable in moist environments, and is better than silica gel for this application [371, 372]. The firebrick method was evaluated under field conditions and found to be superior in handling convenience to the previously used liquid acid impingers.

In addition to the analysis of air samples, furaldehyde derivatization has also been successfully used for the analysis of contamination in ground water [373], but this method is not applicable to MMH, because of incomplete derivatization and instability of the derivative. Instead, MMH in the same matrix has to be derivatized with 2,4-pentadione and analyzed as the pyrazole (see below).

***p*-Chlorobenzaldehyde.** Hydrazine or MMH in urine or blood can be derivatized with *p*-chlorobenzaldehyde, extracted with dichloromethane, and separated by GLC in glass columns with FID [374]. *o*-Chlorobenzaldehyde serves the same purpose for GC analysis with an electron capture detector.

A modification of the method by Timbrell et al. [375] can be used to analyze rat urine for MMH and MMH metabolites containing the  $-NH_2$  group. The modification involved the reaction of *p*-chlorobenzaldehyde (PCBA) to form hydrazones and *p*-chlorobenzaldehyde azine, which were recovered by extraction with dichloromethane. In order to collect the samples, a solution of 25 mg of PCBA in 0.1 mL of methanol was added to each milliliter of freshly voided urine. The derivatized metabolites were extracted using dichloromethane, dried over sodium sulfate, filtered, and concentrated by distilling off the solvent in a rotary evaporator. Prior to analysis by GC, the samples were redissolved in ethyl acetate for injection into the GC with FID. Individual derivative fractions were identified by GC-MS.

**2,4-Pentanedione.** A GC analysis method for trace amounts of hydrazine and/or MMH in water in concentrations of 0.1–50 ppm was based on conversion of hydrazine(s) to the corresponding pyrazole by reaction with pentanedione-2,4 [376]:

The stationary phase was a mixture of 16.7% Amine 220 (Applied Science) and 83.3% Apiezon L (Analabs) on Anakrom ABS. The method was not disturbed by the

presence of UDMH, urea, or alanine, which caused high readings with use of the *p*-dimethylaminobenzaldehyde (PDAB) spectrophotometric method. Interference by  $\text{Fe}^{3+}$  and  $\text{Cu}^{2+}$  ion can be reduced by the addition of  $\text{Na}_2\text{EDTA}$ . Once formed, the pyrazole solutions in water were very stable, and no change in concentration was noted over several months. This method was found to be useful for analysis of trace hydrazine ( $\text{N}_2\text{H}_4$ ) in environmental degradation studies [377]. In these studies it was shown that hydrazine degrades in the presence of atmospheric oxygen ( $t_{1/2}$  approximately 6 h) and in oxygenated aqueous solutions ( $t_{1/2}$  approximately 5 days).

In addition to the analysis of air samples, pentanedione derivatization has also been successfully used for the analysis of MMH contamination in ground water [373]. Separation was on Tenax-packed glass columns and detection was with the use of an FID detector. The detection limit was approximately 1.5 ppm MMH. When soil samples were amended with known amounts of MMH, constant amounts of MMH were not recoverable by acid extraction with 0.9 *N* sulfuric acid owing to irreversible reactions in the soil [378]. The filtered sulfuric acid soil extracts (~200 mL) were immediately derivatized by adding 5 mL pentanedione and adjusting the pH to 9 using 50% NaOH solution. The solution was then diluted to 500 mL with water and immediately analyzed by GC using a Carbowax 20M capillary column, temperature programming, and a thermionic ionization detector. The minimum detectable concentrations in the soil were 0.2 ppm MMH.

**Pentafluorobenzaldehyde.** A quantitative electron-capture gas chromatographic assay procedure was developed for the analysis of monoalkylhydrazines in biological samples [379]. In a further modification of this method, several monoalkylhydrazines including MMH in blood samples were derivatized not only with pentafluorobenzaldehyde to form a hydrazone:

but the remaining N—H hydrogen atom on the hydrazone was also substituted with a pentafluoropropionyl group by reaction with pentafluoropropionic anhydride, further increasing the fluorine content and the detectability of the derivative:

Gas chromatography analysis was then performed on a 30-m fused silica capillary column temperature programmed from 353 to 573 K and an electron capture detector with  $^{63}\text{Ni}$  isotope. Benzylhydrazine was used as an internal standard. Four monoalkylhydrazines were analyzed in whole blood by reaction with pentafluorobenzaldehyde to form stable hydrazone derivatives that were extracted and subsequently reacted with pentafluoropropionic anhydride to give products that were very sensitive to electron-capture detection when analyzed by GC. MMH yielded a single derivative with this procedure, suggesting that the analytical procedure has a broad application to the analysis of other monoalkylated hydrazines.

**Pentafluorobenzoyl chloride.** Traces of MMH found in the mushroom toxin gyromitrin can be analyzed by GC-MS following derivatization with pentafluorobenzoyl chloride [380]. The minimum detectable concentration of MMH by this method was estimated to be approximately 12 pg/ $\mu$ L.

**Pentafluoropropionic anhydride.** MMH in blood can be analyzed following derivatization with pentafluoropropionic anhydride and separation by GC with electron-capture detection [379].

**Chemiluminescence detection.** A Thermedics TEA-510 *N*-nitrosamine detector was interfaced with a modified GC for the specific detection of airborne hydrazine rocket propellant vapors [381]. The analysis involved an *in situ* derivatization followed by GC with chemiluminescence detection. The apparatus consisted of GC equipped with a sample inlet line, a derivatization chamber, delivery systems for the derivatizing agent and reaction catalyst, the TEA-510 chemiluminescence detector, and a PC to process data and control automatic sampling and analysis. Environmental air samples were aspirated into a chamber where trace levels of hydrazines could be extracted and concentrated from air samples for analysis. Derivatization was followed by a separation step utilizing capillary GC. Individual components were then quantified by the chemiluminescent reaction of nitric oxide and ozone. Preliminary results indicated that the system can detect 10 ppb of MMH, with a sampling time of 5 s and a total analysis turnaround time of 27 s. It should be possible to reduce detection limits further by increasing the sampling time.

#### 4.7.3.3 Reaction Gas Chromatography of MMH

The oxidation of MMH with sodium hypochlorite leads to nitrogen, methane, carbon monoxide, and traces of alkyl chlorides. The amount of methane formed is proportional to the amount of MMH present and can form the basis of an indirect GC method for the determination of MMH [382]. The methane produced represented only 25% of theoretical if it is assumed that 1 mol of methane is formed for each mol of MMH reacted. The MMH concentration in the reacting aqueous solution should not exceed 5%, and the lower limit of detectability is 0.3% MMH. The ratio of methane to nitrogen has been used to determine the MMH. This eliminated the day-to-day variation of integrator counts with detector current and effects of equipment aging. It is best to keep the reacting liquid nearly saturated with KCl to minimize solubility of methane in the liquid phase.

Hydrazine/MMH and hydrazine/UDMH mixtures can be analyzed by reactive column GC [383]. Linearity of methane production with sample size could be demonstrated if decomposition occurred on a copper oxide catalyst heated to 573 K. Nitrogen and methane were then analyzed on a 1.8-m  $\times$  6-mm column packed with 30–60 mesh molecular sieve 5A. The methyl substituted component was determined by comparison of the methane peak area with a calibration curve obtained from synthetic blends of the two components. Whereas the hydrazine/MMH mixtures gave a linear methane peak area response between 20 and 80% MMH, the point for pure MMH was not on

the line, and the practically more important 86% MMH mixture was not run, leaving some questions as to the suitability of this method for MHF-3 analysis. In repetitive analysis of 50:50  $\text{N}_2\text{H}_4$ /MMH mixtures, a coefficient of variation of 1.7% (for MMH) was obtained, corresponding to a standard deviation of  $\pm 0.9\%$  relative.

#### 4.7.4 Thin Layer Chromatography of Methylhydrazines

Hydrazine, MMH, SDMH, and UDMH as their dichloride salts can be separated by Thin Layer Chromatography (TLC) on cellulose powder on glass plates, using 2-propanol/water/concentrated HCl in a volume ratio of 130:40:30 as the eluent [384]. Folin–Ciocalteu reagent was used to develop the plates and formed distinct blue spots equally well with all four hydrazines, whereas PDAB did not react with SDMH. Using 366 nm UV light to stimulate fluorescence, hydrazine could be detected at the nanogram level after reaction with fluorescamine and isomeric phthalaldehydes [385]. Two nanograms of MMH from the hydrolysis of gyromitrin in mushrooms was determined by derivatization with PDAB, separation on a glass plate coated with cellulose powder, *n*-butanol/ethanol/water 4/1/2 eluent, and spectrofluorimetric analysis [386].

#### 4.7.5 High-Performance Liquid Chromatographic Analysis Methods for MMH Mixtures

##### 4.7.5.1 High-Performance Liquid Chromatographic Analysis of MMH Without Prior Derivatization

Hydrazine, MMH, UDMH, and SDMH can be separated and determined by ion-exchange high performance liquid chromatography (HPLC) using an electrochemical detector with glassy carbon working and auxiliary electrodes [387]. The hydrazines do not require derivatization and urine or blood plasma samples suspected of containing these compounds may be analyzed directly without previous work-up.

A liquid chromatography-tandem mass spectrometry method for the simultaneous determination of MMH, UDMH, and UDMH decay products used an isocratic mode on an analytical column with a Nucleosil-100-5SA sulfo-cation-exchanger [388]. The mobile phase composition was optimized in order to achieve effective separation of all analytes and provide high sensitivity of mass spectrometric detection. An ammonium acetate buffer solution (50 mM, pH 5.4) containing 25% methanol was used. Detection was performed in the positive electrospray ionization mode with multiple reaction monitoring. The parameters of ion source, ion optics, the inlet potentials of the quadrupoles and the collision energy for the detection of the product ions were optimized. Calibration curves for all compounds were linear in wide concentration ranges, covering 3–4 orders of magnitude. The detection limit was 18 ng/mL for MMH.

A hydrophilic interaction liquid chromatography method for the simultaneous determination of hydrazine, MMH, and UDMH in natural waters and soils was based on a combination of HPLC chromatographic separation on a zwitterionic sulfobetaine

stationary phase with amperometric detection and used a mixture of 78 vol. parts of acetonitrile with 22 parts of an aqueous phosphate buffer solution of pH 2.5 with an ionic strength of 20 mM as the mobile phase [389]. Detection in the direct current mode was performed at a working electrode potential of 1.1 V. The advantages of the method are the high efficiency of separation, speed, high sensitivity, and a wide dynamic range of analyte concentrations, covering four orders of magnitude. The limits of detection were within the range 0.07–0.13 µg/L, which was two orders of magnitude lower than those achievable in previously used methods of ion chromatography with electrochemical or mass spectrometric detection. The method was validated on samples of natural waters of different origin with added internal standards. The error of analysis did not exceed 10% for river and ground waters but increased to 20–30% for peat bog swamp waters. The utility of the method was demonstrated with samples of peat bog soils collected from places polluted by UDMH from the impact of the first stages of space launch rockets.

#### 4.7.5.2 High-Performance Liquid Chromatographic Analysis of MMH With Prior Derivatization

Just as with GC, derivatization of MMH stabilizes it as a derivative for the subsequent separation and analysis by liquid chromatographic methods. Most of the derivatizing agents described for hydrazine in *Encyclopedia of Liquid Fuels*, chapter “Hydrazine” have also been tried for analysis of MMH. Several of the derivatizing agents, for instance, 2-nitrobenzaldehyde, have been shown to work equally well for all three hydrazines,  $N_2H_4$ , MMH, and UDMH [390]. The lower limits of quantitation of MMH and UDMH were 10 ng/mL and that of hydrazine was 1 ng/mL.

MMH, UDMH, and hydrazine can be separated and analyzed after derivatization with naphthalene-2,3-dialdehyde and the separation of the derivatives on a Zorbax Eclipse AAA column in a single HPLC run under acidic conditions (pH 2.4) [391]. Hydrazine and MMH derivatives were found to be strongly fluorescent at  $\lambda_{ex} = 273$  nm,  $\lambda_{em} = 500$  nm. Limits of detection were 0.05 µg/L for MMH or hydrazine for an injection volume of 100 µL.

#### 4.7.6 Ion Chromatography for Analysis of Methylhydrazines

Analysis by ion chromatography uses equipment similar to HPLC. Ion chromatography is often performed in the same equipment as HPLC, just using ion-exchange resins instead of solid sorbents as the stationary phase. Ion chromatography can use cation-exchange resins or anion-exchange resins. A major drawback of the commonly used derivatizing agents for either GC or HPLC is that they rarely allow analysis of all three propellant hydrazines in one shot. It was therefore of interest when it was found that all three hydrazines, underivatized but in the state of their cations, could be separated by HPLC on a cation-exchange resin column using an acidic potassium phosphate buffer as the eluent [392]. DC amperometry of the eluent at a platinum elec-

trode is specific for hydrazines as they are easily electro-oxidized. Detection limits of  $1\text{ }\mu\text{g/L}$  were achieved in clean waste water samples. The only sample preparation was filtering, a substantial saving of labor over competing derivatizing/extracting methods. Similar results are possible with a gold electrode [393]. This method gave three cleanly resolved peaks for the three hydrazines within the concentration range 3 ppm each (Figure 29). The operating conditions were: Column:  $250 \times 4.1\text{ mm}$  Hamilton PRP-X200, Mobile phase: 5-M  $\text{KH}_2\text{PO}_4$ , 6% acetonitrile, Injection:  $25\text{ }\mu\text{l}$ , Flow:  $1.0\text{ mL/min}$ , Detection: Pulsed amperometric detection, gold electrode.

**Figure 29:** Ion chromatogram of hydrazine, methylhydrazine, and unsymmetrical dimethylhydrazine. (Reproduced and modified from [393].)

Hydrazine and hydroxylamine in aqueous solution may be determined using a Nucleosil 10SA cation-exchange column with 2mM citrate and 2mM ethylenediamine at pH 4.5 as eluent with a copper electrode [394]. Detection limits were within the range 2–10 nmol for the species examined.

Ion chromatography with amperometric detection was applied for direct determination of hydrazine, MMH, UDMH, and SDMH in water [395]. Selectivity of two column materials: **(1)** reversed phase silica modified by dodecylbenzenesulfonic acid and **(2)** silica with chemically bonded sulfonic acid groups was investigated using con-

ductivity detection. Retention of hydrazines was found to be similar to that for alkylamines with the same structure. Hydrazines have to be completely protonated in the mobile phase; therefore, an eluent buffer solution with pH less than 7.0 should be chosen. Mobile phase composition (buffer type, pH) and applied potential used for amperometric detection were optimized from the viewpoint of separation selectivity and detection sensitivity. The application of a phosphate buffer with pH about 7 and potential +1.0 V were recommended for the best results. An example for separation of the four hydrazines is shown in an ion chromatogram image in the UDMH section of the chapter “Dimethylhydrazines” in the present set *Encyclopedia of Liquid Fuels*. Detection limits with a 0.5-mL sample injection for hydrazine, MMH, UDMH, and SDMH were 0.4, 0.6, 2.0, and 1.0 ppb respectively.

The ion-exchange constants for ion-chromatographic retention of 16 aliphatic amines and hydrazines on Diasorb-130-Sulfo and Nucleosil 5 SA were calculated and the selectivities of the retention of these compounds were compared. The optimal conditions of detection were then determined [396]. MS detection was used for compound identification after the chromatography separation and the characteristics of the mass spectra of the aliphatic amines and hydrazines were discussed.

There are several methods for the direct determination of hydrazines in water, including ion, ion-pair, ion-exclusion, and hydrophilic interaction chromatography [397]. The separation selectivity and sensitivity of detection for each method depends on the type of samples. Direct methods are simpler than those requiring prior derivatization of the samples, as was demonstrated with examples of hydrazine(s) determinations in real samples.

#### 4.7.7 Capillary Electrophoresis Chromatography of Methylhydrazines

Another modern analysis procedure suitable for the analysis of ionized compounds is capillary electrophoresis (CE). This CE method in combination with electrochemical detection (called “CEEC”) allows the simultaneous determination of hydrazine and MMH in one injection without prior derivatization [398]. Detection of hydrazines in the eluent was achieved with a palladium-modified carbon fiber micro-disk array electrode. The detection limits for hydrazine or MMH were 1.2 and 2.1 pg respectively. This is several orders of magnitude more sensitive than other chromatographic methods. Hydrazine and methylhydrazines could be separated and detected at 1 millimol/L concentrations in a borate buffer at pH 7.18 [399].

Poly(methyl methacrylate) microchip electrophoresis separations with contactless conductivity detection, which integrates all separation and detection components in a compact portable device, enables the separation of hydrazine, MMH, and UDMH within <30 s at a separation voltage of 3.8 kV using a L(–)-histidine/2-(N-morpholino)-ethanesulfonic acid buffer (25:50 mM, pH 5.87) [400]. The contactless conductivity detection enabled detection limits for hydrazine, MMH, and UDMH of 11.9, 35.5, and 337.8 ng/mL respectively, with linear concentration dependence up to 10 µg/mL. In complex matrices such as soil samples or river water, interferences were eliminated

by implementing ultrasound-assisted headspace single-drop microextraction under strongly alkaline conditions, which led to improved limits of detection for hydrazine, MMH, and UDMH of 6.5, 15.3, and 11.4 ng/mL respectively.

#### 4.7.8 Volumetric Analysis Methods for MMH

Volumetric, titrimetric analysis methods have traditionally been the daily chore of the analytical chemist before wet chemistry was eventually replaced by automated titrators and instrumental methods of analysis where one does not have to wash dishes afterward. As they are listed here, volumetric analysis methods only differ by the type of reaction and endpoint indication.

##### 4.7.8.1 Acidimetric Titrations of Methylhydrazines

An analytical method for determining mixtures of either hydrazine and 1,1-dimethylhydrazine ( $\text{N}_2\text{H}_4$ /UDMH) or MMH and 1,1-dimethylhydrazine (MMH/UDMH) was based on the difference in reaction rates for acetylating hydrazines with acetic anhydride [355]. Both  $\text{N}_2\text{H}_4$  and MMH reacted immediately, whereas the acetylation of UDMH proceeded only slowly. The UDMH was slow to react even when a considerable excess of acetic anhydride was added:

The reactions were conducted in an acetonitrile-acetic acid medium. Two titrations are required: one measured the total basicity of the hydrazine mixtures by titration with perchloric acid in acetic acid and quinaldine red as the indicator and the other titration measured UDMH after the  $\text{N}_2\text{H}_4$  or MMH has reacted with  $\text{Ac}_2\text{O}$ . Increasing the water content (1 to 7.8%) did not interfere with the titration. Both the potentiometric and visual quinaldine red indicator endpoints were evaluated.

An investigation of the salicylaldehyde derivatization/acidimetric titration method showed that the species actually titrated in the mixture of hydrazine and methylhydrazines are the free MMH and the free UDMH and that low recovery rates are the result of incomplete hydrolysis of any hydrazone present during the titration [401]. When an excess of perchloric acid was included in the salicylaldehyde reaction mixture, hydrolysis was complete, and even MMH could be determined. For the analysis of hydrazine/MMH mixtures, the sample (~0.4 g) is added to 35 mL of chilled glacial acetic acid in a 50-mL volumetric flask. After equilibration to room temperature, the sample is diluted to the mark with more acetic acid. An aliquot is then added to 50 mL of acetic acid, an excess of 0.1N perchloric acid is added, and the excess is back-titrated with 0.1N sodium acetate in acetic acid, using potentiometric endpoint indication. The first titration gives total alkalinity, whereas subsequent titration on another aliquot after the addition of 2 mL of salicylaldehyde

titrates MMH only. The procedure was tested by analyzing synthetic mixtures of hydrazine and MMH over a wide range of compositions from 0 to 100% MMH. The error rarely exceeded 1% absolute. If the reaction products with salicylaldehyde were left standing too long in the acetic acid/perchloric acid mixture prior to the titration with sodium acetate, even the azine would eventually hydrolyze. After 24 h, 80% of the azine was hydrolyzed to hydrazone and salicylaldehyde, as indicated by UV spectra taken of monomethylhydrazone of MMH and azine of hydrazine before and after addition of perchloric acid.

Hydrazine and its methylated derivatives can be differentiated not only by reaction with acetylating agents or azine-forming reagents but also by acidimetric titration before and after reaction of the sample with isocyanates [357, 402]. The reaction of hydrazines with alkyl or aryl isocyanates leads to semicarbazides, which are weaker bases than the parent hydrazines. In alcoholic solution, hydrazine, MMH, and UDMH react with isocyanates at approximately the same rate to form semicarbazides. In contrast, in anhydrous acetic acid, hydrazine and MMH react rapidly, but UDMH reacts hardly at all. Suitable isocyanates for masking hydrazine or MMH are phenyl isocyanate or naphthyl isocyanate.  $\text{N}_2\text{H}_4/\text{UDMH}$  and  $\text{N}_2\text{H}_4/\text{MMH}$  mixtures were titrated by this method, and the error very rarely exceeded 0.5% absolute.

#### 4.7.8.2 Redox Titrations of Methylhydrazines

Because of the multitude of oxidizers that have been more or less successfully tried as oxidants for the redox titrations of alkylhydrazines, a systematic approach should be followed in discussing these analysis methods. The following discussion covers redox titrations in the sequence of groups in the periodic table of elements, arranged by the active atom that changes its state of oxidation.

Hydrazine nitrogen in monosubstituted organic hydrazine derivatives can be determined by potentiometric titration with potassium iodate, which may go to different states of reduction of iodine(V), depending on the pH [403].

In evaluating several different methods for analysis of hydrazine and its methyl derivatives by redox titrations, both iodate and bromate titrations were conducted for hydrazine, MMH, UDMH, and SDMH [404]. In the iodate titration using a layer of chloroform and extraction as a visual endpoint indicator, hydrazine reacted on a 1:1 molar basis, but UDMH reacted on an iodate:UDMH = 1:2 and SDMH on a 3:2 basis. As an alternative, the four hydrazines can be titrated potentiometrically with 0.016 M  $\text{KBrO}_3$  when the samples are dissolved in 20 mL of concentrated HCl containing 2 g of KBr.

Methylhydrazine can be titrated with potassium iodate by titration with iodate in acidic medium [405]. The reaction of MMH is assumed to proceed by way of

Methanol does not become oxidized under these conditions and methanolic/aqueous iodate solutions gave the same results as titrations in pure water. Mixtures of hydrazine and MMH are analyzed by a first titration, which gives the total of hydrazine and MMH equivalents. Then, in a second sample, following reaction of hydrazine with

salicylaldehyde and removal of the precipitate, the remaining MMH is titrated with  $\text{KIO}_3$  [406]. The same method can also be used for hydrazine–UDMH mixtures. In this case the reaction goes to tetramethyltetrazene:

The method can even be applied to ternary mixtures of hydrazine, MMH, and UDMH. In this case, three aliquots are required. The sum of the hydrazines is determined with potassium iodate. The sum of MMH and UDMH is found after selective removal of hydrazine by reaction with salicylaldehyde. Finally, the UDMH content is obtained by acidimetric titration with  $0.1\text{N HClO}_4$  in acetic acid after acetylation of hydrazine and MMH with acetic anhydride in dioxane.

Attempts to apply iodine or iodate redox titration methods (which worked satisfactorily with hydrazine  $\text{N}_2\text{H}_4$ ) to the analysis of MMH or UDMH have not always been successful at the first attempt [355]. Acidity, sample size, temperature, amount of mercury catalyst, and time spent to reach the endpoint must be carefully controlled, with acidity maintained at above  $2\text{N HCl}$ . The endpoint can be detected by the blue color formed by starch with the first free iodine formed from excess iodate and iodide. Potentiometric endpoint indication is also possible.

Mixtures of hydrazine and MMH can be titrated next to each other using a differential method [407]. For this method, three standard reagents, together with several other additives and buffer, were required. First, an aliquot of the mixture is reacted with excess chloramine-T solution to determine the sum of the two hydrazines. In this step, MMH consumes four electrons, just like hydrazine itself. Excess oxidant is back-titrated with sodium thiosulfate. A second aliquot is then reacted with excess sodium hypochlorite in the presence of potassium bromide and a phosphate buffer. In this case, excess oxidant is also back-titrated with thiosulfate. Whereas chloramine-T is a moderately strong oxidant, sodium hypochlorite/hypobromite is a more vigorous oxidant, and the oxidation of MMH with this oxidizer consumes eight electrons. Both hydrazines involved a four-electron change with chloramine-T. With sodium hypochlorite,  $\text{N}_2\text{H}_4$  involved a four-electron change and MMH an eight-electron change. The difference between the two titrations allows one to calculate the amount of MMH present in the mixture:

$$mM\{\text{MMH}\} = \frac{\text{meq}[\text{OCl}^-] - \text{meq}[\text{CT}]}{4}$$

where CT is chloramine-T. Likewise, the amount of hydrazine is:

$$mM\{\text{N}_2\text{H}_4\} = \frac{2\text{meq}[\text{CT}] - \text{meq}[\text{OCl}^-]}{4}.$$

Clark and Smith failed to detect methane in the reaction products of MMH and hypochlorite, but it was later shown that non-stoichiometric amounts of methane are formed in this reaction [382]. Later investigators also reported problems with consistently high and otherwise erratic results with this method [401].

Oxidizer titrants that give clear-cut reactions with hydrazine may not always give unequivocal answers when used for the titration of MMH or UDMH, because of the involvement of the methyl groups that can be oxidized to different levels. Potassium iodate, ferric salts, potassium permanganate, periodic acid, and iodine were investigated as oxidizing agents for the quantitative determination of UDMH [408]. Titrations with potassium iodate were made to the iodine monochloride equivalence point in hydrochloric acid, to the iodine equivalence point in sulfuric acid, and to the iodide equivalence point in the presence of mercuric salts.

#### 4.7.9 Electrochemical Analysis Methods for MMH

Electrochemical analysis methods are becoming increasingly popular because they can be automated and would eventually interface with digital data acquisition and data reduction.

##### 4.7.9.1 Coulometric Analysis Methods for MMH

A rapid and automatic coulometric titration procedure for the determination of hydrazine and monosubstituted hydrazines with electrolytically generated bromine had a standard deviation of approximately  $\pm 1\%$  and was based on the use of the Faraday constant as a standard [409]. Samples in the 3–5-mg range could be analyzed. The use of anodically generated chlorine in place of bromine did not result in any improvements. An acetic acid/water/methanol/mercury(II)acetate/potassium bromide solvent was used for most of the compounds titrated. Other solvents tested were aqueous 0.3M hydrochloric acid with 0.1M potassium bromide and 80% acetic acid/20% water 1.0M in hydrochloric acid with potassium bromide. The choice of solvent depends on the type of hydrazine to be titrated. Hydrazine or MMH consumed close to four equivalents of bromine, and the reaction was rapid.

Improved accuracy for monitoring the air in places of employment, and a very wide dynamic range, is possible by analyzing impinger samples by coulometry with electrogenerated bromine in sulfuric acid. For MMH vapor collected in 40 mL of 0.1N  $\text{H}_2\text{SO}_4$  in an impinger by passing 10 L of air, the detection limit was an astounding 2 ppb corresponding to 25 ng of MMH [410]. This method constituted an improvement of the Olson [409] method. The dynamic range of the improved method extended from 25 to 2500 ng MMH. This method has also been used for the analysis of scrubber liquid from large citric acid-filled scrubbers through which vented nitrogen gas was passed after transferring fuel into the space shuttle and depressurizing the transfer tanks [411]. Ammonia was found to be a potential negative interferent. The higher the ammonia in the sample stream, the lower was the amount of the analyte detected in the scrubbed solutions, i.e., 25 and 58% average detection loss at 50 and 588 ppm levels of ammonia respectively.

Direct coulometric titration of hydrazine, MMH, or acetylhydrazine with electrically generated bromine in acetic acid gave reproducible results [412]. It was shown

that 0.9M  $\text{CH}_3\text{COONa}$  or  $\text{CH}_3\text{COOK}$  dissolved in glacial acetic acid provided a good anode electrolyte. Contamination by no more than 4% water could be tolerated, but none by acetanhydride.

#### 4.7.9.2 Potentiometric Analysis Methods for MMH

An electrochemical cell capable of detecting threshold limit values (TLVs) of hydrazine, MMH, or UDMH in air was coupled with a dynamic air-sampling system and electronic control and amplification circuitry to provide a direct-reading portable analyzer [413]. Although most of the reported data were specifically for MMH vapor analysis, qualitatively similar results can be obtained when using this instrument for hydrazine or UDMH measurements.

#### 4.7.9.3 Polarographic Analysis Methods for Alkylhydrazines

A measurement of the half-wave potentials of hydrazine, six alkylhydrazines and phenylhydrazine in 0.1M NaOH showed that the half-wave potential was shifted to more negative voltages with increasing length of the carbon skeleton in the alkyl group [414].

The half-wave potential of monosubstituted alkylhydrazines depends linearly on the length of the hydrocarbon chain [415]. Polarography in 2N  $\text{H}_2\text{SO}_4$  and in sodium pyrophosphate at pH = 6–7 on a platinum electrode showed that the potential decreased 60 mV per carbon atom in acidic and 48 mV per carbon atom in neutral solution. In methylhydrazines with progressive methyl substitution, the potential changed +20 mV per added methyl group in acidic and +80 mV per methyl group in neutral solution. All methylhydrazines were oxidized with the loss of four electrons, except SDMH in both media and UDMH in neutral solution, where the oxidation was only a two-electron transfer.

Using more advanced equipment, a hanging mercury electrode, and a commercial voltammetric analyzer with a stationary glassy-carbon disk anode, it was shown that the simultaneous addition of formaldehyde and catalytic amounts of platinum salts give sensitive and specific cyclic voltamperograms for all three propellant hydrazines (singly, not in admixture) at concentrations down to  $10^{-6}$  M [416].

Hydrazines can be determined by voltammetry, based on their hydrogen catalytic wave in formaldehyde–platinum–sulfuric acid media [417]. Adsorption of the platinum–formazone complex on the hanging mercury drop electrode enhanced the sensitivity, allowing convenient measurement of micromolar and submillimolar concentrations of simple hydrazines. The selectivity was better than that of conventional (anodic) measurements of hydrazine(s), as oxidizable compounds did not interfere. The sensitivity was also greatly improved. The hydrazine(s) response was evaluated with respect to preconcentration time, concentration dependence, platinum and formaldehyde concentrations, reproducibility, and other variables. The relative standard deviation (at  $2 \times 10^{-5}$  M) was 1.6%.

#### 4.7.9.4 Amperometric Analysis Methods for MMH

Mesoporous silica that was prepared by a sol-gel process was used as the electrolyte for the amperometric determination of vapor-phase MMH [418]. Three detection strategies were tested, namely cyclic voltammetry at a Pt working electrode with the oxidation mediated by  $\text{Fe}^{\text{II,III}}$  that was hosted by the silica, pulsed electrochemical detection with a gold working electrode, and potentiostatic oxidation at a mixed-valence ruthenium oxide film that was deposited on a Pt working electrode. The sensitivities (and linear dynamic ranges) for the three methods were determined. A cell design that provided a three-phase boundary at a mixed-valence ruthenium, oxide-modified electrode yielded a swift response of 90% of the steady-state current within 11 s.

#### 4.7.10 Spectrophotometric Analysis Methods for MMH

##### 4.7.10.1 UV/Visible Spectrophotometric Analysis Methods for MMH

Many of the spectrophotometric methods operating within the visible range have the advantage of being easy to perform, are specific for hydrazines, and do not require very costly equipment. Therefore, for analysis of trace quantities of MMH in air or water, spectrophotometric methods are frequently used, either for routine analysis or to calibrate electronic direct-reading instruments that are based on non-spectroscopic principles. They typically involve the reaction of a sample in water or dilute acid with a color-forming reagent that is more or less specifically for MMH. Hydrazines and amines (only in the state of the free base, not their salts) form intensely colored adducts ("Meisenheimer complexes") with aromatic nitro compounds that may be suitable for qualitative detection of MMH or UDMH [419].

The spectrophotometric determination of hydrazine with *p*-dimethylaminobenzaldehyde (PDAB for short, sometimes also abbreviated to PDBA) is without any doubt the most widely used spectrophotometric analysis method for the determination of small quantities of hydrazine in air or water [420] and can also be used for determination of MMH. The PDAB method was applied to the analysis of microgram quantities of MMH in the blood serum of rats [421, 422]. Calibration curves covered the range 0.5–10  $\mu\text{g}$  of MMH. Minimum detectable dosage in blood serum was 3 mg/kg of MMH administered intraperitoneally. Blood specimens were collected at intervals of 1, 2, 4, and 6 h after injection. There was no interference by protein, urea, or uric acid.

The PDAB spectrophotometric method can also be used for the determination of MMH [405]. The yellow compound is believed to have a *p*-quinone-type structure similar to the highly colored hydrazine–PDAB compound, except with only one benzene (quinone) ring in the molecule:

The measurements were carried out at 458 nm, and determination errors of 1.6% relative were encountered. MMH stored in the form of the sulfate salt had to be recrystallized prior to preparing the standards, because yellow impurities accumulated on the outside of the crystals, most likely from air oxidation.

Methylhydrazine in blood or plasma samples can be analyzed by using the PDAB reagent and an automated analyzer such as the Technicon Autoanalyzer [423]. Such instruments are frequently used in clinical laboratories for routine analysis. The absorption at 480 nm was used for quantitation. The method was found to be accurate and reproducible in biological samples within the range 1–40 µg per sample. The apparatus was capable of automatically analyzing 40 samples per hour. The PDAB reagent concentration was 8%, dissolved in ethanol (instead of methanol, which gives lower sensitivity). Color development and stabilization was achieved by adding glacial acetic acid. Reliable analysis of blood MMH required prompt centrifugation to stop conversion of hemoglobin to methemoglobin. Immediately after centrifugation, the serum was removed and stored in a capped vial. Stored in this manner, the sample was stable for several days in the refrigerator. The catalytic activity of freshly washed red blood cells (RBCs) was demonstrated by incubation with MMH solution. Fifty percent of the MMH was destroyed in the first 10 min.

5-Nitro-2-furaldehyde was introduced as a derivatizing agent for the spectrophotometric determination of hydrazine, MMH, and UDMH [424]. It is characterized by high solubility in water and by a substantial difference in the positions of absorption bands of the three colored derivatives formed. The kinetics of the reaction of analyte derivatization were studied in order to optimize reaction conditions (pH 5, concentration of derivatizing agent 2 mM, 333 K = 60 °C, color development duration 40 min). The limits of detection were 5, 3, and 1.5 µg/L for hydrazine, MMH, and UDMH respectively.

#### 4.7.10.2 IR/Raman Spectrophotometric Analysis Methods for MMH

Water obeys Beer's law in liquid hydrazine hydrate, MMH, or UDMH. Using the 1.9-µm absorption band of water, an IR-spectrophotometric analysis method has been developed that is applicable to mixtures containing 0.1–15% water [425]. Dimethylamine or nitrosodimethylamine do not interfere, but methanol or ethanol would interfere if they were present in concentrations greater than 1%. One-centimeter quartz cells were used for these tests. The results can be expressed by  $P = a + bA$ , where  $P$  represents weight percent of water in the mixture,  $A$  is 100 times the absorbance, and  $a$  and  $b$  are constants as follows (all data for 1-cm path length):

|                               |               |                |
|-------------------------------|---------------|----------------|
| N <sub>2</sub> H <sub>4</sub> | $a = -0.053$  | $b = 0.1057;$  |
| MMH                           | $a = -0.0062$ | $b = 0.01958;$ |
| UDMH                          | $a = 0.019$   | $b = 0.01994.$ |

If the sample temperature differed by less than 2 K from that used during calibration, only minor deviations (<1%) were encountered. Oxygen must be excluded from the

solutions to prevent autoxidation and formation of additional water. A similar method used IR spectrophotometry for both water at 1.9  $\mu\text{m}$  and aniline at 6.66  $\mu\text{m}$  [426].

As far as the analysis of trace MMH and other hydrazine vapors in air by remote sensing IR methods is concerned, some of these methods are based on a tunable laser as the source of the IR radiation. The  $^{12}\text{C}^{16}\text{O}_2$  laser can produce over 100 different discrete wavelengths between 9.1 and 11  $\mu\text{m}$ , where there is very little interference from atmospheric water or carbon dioxide. Hydrazine, MMH, and UDMH have characteristic absorption bands in this regime [427]. The absorption spectra of three hydrazines and four of their air-oxidation products were measured in the 9–12- $\mu\text{m}$  spectral region with an FTIR spectrometer with a  $0.05\text{-cm}^{-1}$  resolution to determine absorption coefficients at  $\text{CO}_2$  and tunable diode laser wavelengths. The measurements agreed well with published  $\text{CO}_2$  laser determinations for many of the absorption coefficients, except where the published values were thought to be in error. The coefficients were then used to estimate the sensitivity for remote detection of these vapors using  $\text{CO}_2$  and tunable diode lasers in long-path differential absorption measurements.

Trace MMH and other hydrazine vapors in air can be detected by laser absorption or even by remote sensing techniques using Light Detection and Ranging (LIDAR) [428, 429]. Absorption cross-section data were measured for hydrazine, MMH, and UDMH vapors, as well as for their selected air oxidation products dimethylamine, trimethylamine, and methanol at up to 78  $\text{CO}_2$  laser wavelengths each [430]. These data are important for the assessment of the capability of  $\text{CO}_2$  laser-based spectroscopic techniques for monitoring low levels of hydrazine(s) fuel vapors in ambient air. Interference-free detection sensitivities of <30 ppb have been demonstrated for UDMH using a laboratory photoacoustic detection system.

The high-resolution laser radiation absorption cross-sections of hydrazine, MMH, UDMH, and their oxidation products were determined first in order to assess the value of the laser techniques [431]. In addition to IR absorption or LIDAR fluorescence, photoacoustic detection of hydrazines has been studied by pumping modulated energy into selected wavelengths of vapors in a cell with a microphone [432] (see Section 4.7.13). Absorption of energy by the vapor in question causes a temporary pressure pulse (=sound), which can be picked up by the microphone [433]. With a laser output at 1 W/line, the photo-acoustically detectable levels are 0.2, 0.3, and 0.3 ppb for hydrazine, MMH, and UDMH respectively. In comparison, for simple long-path-length (100-m cell) absorption, the sensitivities would be “only” 70, 140, and 130 ppb respectively. For LIDAR, remote sensing detection limits for the three hydrazines vary between 20 and 90 ppb. With polluted urban air as a background, detection limits would be significantly worse. Most laser methods would suffer one to two orders of magnitude in sensitivity if hydrazines had to be detected against a background of urban atmospheric pollutants. Another IR method (so far used mostly for detection of chemical warfare agents) relies on the blackbody radiation of buildings, rocks, or soil in the background of a radiometer-scanned area to provide

a source of radiation. A hydrazine vapor cloud drifting between the background horizon and the observation site can be detected by its IR absorption [434].

A laboratory prototype dual He-Ne laser system that was so far only used for the detection of methane leaks from underground pipelines and solid-waste landfill sites using differential absorption of radiation backscattered from topographic targets can also be used for detection of hydrazine fuel vapors and sense the presence of a vapor coming from a nearby source [435–437].

#### 4.7.10.3 Spectrofluorescence Analysis Methods for MMH

Fluorescence of solid or liquid samples excited with light of shorter wavelength can be very specific for certain hydrazine derivatives and is suitable for detection of trace quantities, such as hydrazine derivatives on a thin-layer chromatography plate.

2,3-Naphthalenedicarboxaldehyde forms derivatives with hydrazine that fluoresce intensely and give linear response within the range 50 to 500  $\mu\text{g}$  hydrazine [438–440]. In combination with a liquid absorbent/air concurrent contactor this allows real-time measurement of hydrazine(s) concentrations of less than 10 ppb in air. Three aromatic 2,3-dicarboxaldehydes were tested for the fluorescence of their hydrazine derivatives, *o*-phthalaldehyde (OPA), 2,3-naphthalenedicarboxaldehyde (NDA), and 2,3-anthracenedicarboxaldehyde (ADA). Incorporating MMH into the aromatic framework of benzene, naphthalene, or anthracene and adding another fused heterocyclic ring give highly efficient fluorophores (analog to chromophores). The derivatization of MMH with OPA, NDA, or ADA creates an efficient fluorophore the emission wavelength of which is red-shifted from the original reagent. The fluorescence emission for each of the different derivatizing reagents (OPA, NDA, and ADA), is minimal and nearly within the noise of the background. The hydrazine derivatives, on the other hand, are intensely fluorescent and characterized by a broad fluorescence emission centered at 376 nm for OPA, 500 nm for NDA, and 549 nm for ADA. By careful control of the pH and the aromatic dicarbaldehyde chosen, it is possible to differentiate quantitatively among the hydrazine, MMH, and UDMH levels present in mixed samples. The detection limits for MMH and UDMH using the NDA reagent are 120 ng/L and 40  $\mu\text{g}$ /L respectively [441, 442].

#### 4.7.11 Mass and Ion Mobility Spectrometric Analysis of MMH

Mass spectrometric analysis of alkylhydrazines is used extensively for trace detection, for the study of decomposition or oxidation kinetic mechanisms, or for the determination of molecular structure data. The simultaneous detection of MMH and NTO by MS is complicated by the fact that both propellants have the same molecular mass (46). The ionization and appearance potentials of several molecule fragments are summarized in Table 36 and 37. This will be an aid to future investigators in the identification of *m/e* peaks [443]. Some of the appearance potentials were determined by photoelectron ionization methods.

**Table 36:** Summary of ionization potentials of alkylhydrazines.

| Fragment                           | Ionization potential, eV | References |
|------------------------------------|--------------------------|------------|
| HN=NH                              | $9.85 \pm 0.1$           | [444]      |
| HNNCH <sub>3</sub>                 | $9.28 \pm 0.1$           | [200]      |
| HNNHCH <sub>3</sub>                | $7.3 \pm 0.2$            |            |
| HNN(CH <sub>3</sub> ) <sub>2</sub> | $6.4 \pm 0.2$            |            |
| HNN(CH <sub>3</sub> ) <sub>2</sub> | $6.6 \pm 0.3$            |            |
| N(CH <sub>3</sub> ) <sub>2</sub>   | $9.42 \pm 0.1$           | [445, 446] |

**Table 37:** Summary of appearance potentials of hydrazine and methylhydrazines.

| Species                                           | Parent compound               | Appearance potential, eV | References |
|---------------------------------------------------|-------------------------------|--------------------------|------------|
| N <sub>2</sub> H <sub>4</sub> <sup>+</sup>        | N <sub>2</sub> H <sub>4</sub> | 10.07                    |            |

In many instances not only is the hydrazine molecule dissociated but the ion is also left in a state of excitation from which a photon may be emitted. The state of excitation is indicated either by letters in parentheses or by an asterisk\* following the formula of the ion. The calculated ionization potential of N<sub>2</sub>H<sub>4</sub> is 7.54 eV, in agreement with experimental data.

Although the mass spectrometry of hydrazine itself seems to be a fairly straightforward approach, mass spectra of organic hydrazines can be very complex. High-resolution mass spectra of MMH were recorded in order to distinguish between different fragment ions of the same unit mass [279, 280]. Another objective of these tests was to obtain the effective cross-sections of hydrazine molecules in the electron beam ionizer section of a mass spectrometer [451].

The main pathway of electron-impact decomposition of 40 different monoalkylhydrazines tested was not N–N cleavage but β-cleavage [452, 453]. When secondary or tertiary alkyl groups were present, α-cleavage was sometimes accompanied by hy-

drogen migration. Di- and trialkylhydrazines were studied in a similar fashion with similar results.

Fragmentation of triaryl hydrazines under electron impact was described as a retro-addition process that leads to a diazenium cation and an olefin [454]. Another fragmentation mode involved the breaking of the N—N bond.

Mass spectra of methyl-, ethyl-, propyl-, and other monoalkylhydrazines ionized in a strong electric field showed C—N cleavage with retention of the charge on both fragments,  $\text{N}_2\text{H}_4^+$  formation by way of intramolecular rearrangement, and no simple N—N cleavage [455]. The mass spectra of substituted hydrazines showed lines of fragments corresponding to cleavage of C—C bonds with simultaneous migration of a hydrogen atom from one fragment to another. In saturated alkylhydrazines, cleavage of the  $\alpha$  C—C bonds takes place with migration of a hydrogen atom from the nitrogen-containing fragment to the paraffinic fragment.

Formaldehyde hydrazone  $\text{H}_2\text{C}=\text{NNH}_3^+$  and its isomeric  $\text{C}_1\text{H}_5\text{N}_2$  monocations and hydrazyl radicals are intermediates in the decomposition and oxidation of MMH [456]. Isomeric  $\text{CH}_5\text{N}_2^+$  cations, radicals, and dication radicals have been studied by a variety of mass spectrometry-based techniques (metastable ion-, collisional activation-, collision-induced dissociative ionization-, neutralization-reionization-, charge stripping/charge separation-, and charge stripping/electron-capture-induced decomposition mass spectroscopy), by energy measurements and labeling experiments. Four distinct singly charged ions could be identified: **(1)**  $\text{H}_3\text{C}-\text{NH}-\text{NH}^+$ , **(2)**  $\text{H}_3\text{C}-\text{N}-\text{NH}_2^+$ , **(3)**  $\text{H}_2\text{C}-\text{NH}-\text{NH}_2^+$ , and **(4)**  $\text{H}_2\text{C}=\text{N}-\text{NH}_3^+$ . Ions (1), (2), and (3) are generated by direct bond cleavage reactions in 1,2-dimethylhydrazine, 1,1-dimethylhydrazine and 2-hydrazinoethanol molecular ions, respectively. Ion (4), it was proposed, was formed by isomerization of (3). There is a possibility that (3) and (4) collapse to the bridged structure:

Metastable  $\text{CH}_5\text{N}^{+2}$  ions fragment to  $\text{NH}_4^+ + \text{HCN}$  and to  $\text{HC}=\text{NH}^+ + \text{NH}_3$ . An atlas of mass spectra of organic compounds contains numerous mass spectra of organic hydrazine derivatives [457].

Unsymmetrical dimethylhydrazine, MMH, and hydrazine in air can be detected and identified by ion mobility spectrometry (IMS) at low concentrations, but with interference from ammonia [458]. The optimal spectrometer operating conditions, for the detection of hydrazine, MMH, and UDMH in the presence of ammonia were incorporated into a hand-held portable instrument capable of near real-time detection. Ammonia is still an interferent in the IMS detection of the parent hydrazine. The use of ketones as dopant chemicals has been shown to be effective in the ion mobility spectrometric determination of the hydrazines.

The unimolecular dissociation reactions of ionized MMH,  $\text{CH}_3\text{NHNH}_2^+$ , 1,1-dimethylhydrazine,  $(\text{CH}_3)_2\text{NNH}_2^+$ , and tetramethylhydrazine,  $(\text{CH}_3)_2\text{NN}(\text{CH}_3)_2^+$ , were investigated using tandem MS, threshold photoelectron photo-ion coincidence spectroscopy, and variational transition state theory [197]. The modeled thresholds for the ion dissociation yielded new thermochemistry for these  $\text{N}_2$ -containing ions. The low-energy dissociation pathways of the methyl-substituted hydrazine radical cations correspond to the losses of a hydrogen atom, a methyl radical, and/or a rearrangement process leading to the loss of methane.

#### 4.7.12 Proton Magnetic Resonance Analysis of Methylhydrazines

The Proton Magnetic Resonance (PMR) signals of protons contained in amino, methyl, or dimethyl groups differ sufficiently to allow a quantitative determination of hydrazine, MMH, and UDMH in binary or ternary mixtures. All four possible combinations can be handled by a single PMR scan [459]. Tetramethylsilane was used as internal standard. Water interferes because the rate of proton exchange between the hydrazines and water is fast enough to wash out the sharpness of the peaks. The actual measurement takes less than 10 s. To calculate the percentage of hydrazine, MMH, and UDMH in the mixture, the relative areas under the  $-\text{NH}_2$  and  $-\text{CH}_3$  peaks were measured, corrected statistically to area per proton, and inserted into simple data reduction equations. The method was tested on 27 different mixtures, and the average absolute deviation in molar fraction was less than 0.01.

#### 4.7.13 Trace Analysis of MMH Vapors in Air

Because the olfactory threshold for MMH vapor is above the concentration at which permanent damage can be caused by continued MMH inhalation, it is very important to monitor workplaces with sensitive analytical devices. One cannot rely on the human sense of smell alone to receive a warning when dangerous MMH concentrations are exceeded. This applies to hydrazine itself as well as many volatile hydrazine derivatives. The methylhydrazines have a more pronounced (“fishy”) odor and are more readily detected than hydrazine itself.

The olfactory threshold for hydrazines is discussed in Section 11.14. Analytical methods are now needed that are more sensitive than our noses and provide a more quantitative answer. The sensitivity requirements for MMH detection instrumentation are inevitably tied in with the TLVs and emergency exposure limits (EELs) established by various government agencies for the protection of workers inside and the general public outside of the factories and test sites. The two sets of numbers, the instrument sensitivity capability and the government maximum allowable limit, seem to “leapfrog” each other where the government regulators are reasonable enough not to establish limits so low that they cannot be verified, but nevertheless often set them so low that each lowering constitutes a new challenge to the instrument industry. The limits for hydrazines have been lowered twice by several orders of magnitude within

the past three decades. Therefore, the instrument industry was constantly struggling to come up with instruments that could reliably detect the new TLVs or even fractions of the new TLVs to provide some level of confidence or to be prepared for the next imminent lowering of the TLV. To the uninvolved bystander it sometimes looked as if the availability of more sensitive detection methods (more sensitive than the current TLV) spawned a new round of calls from the occupational hygiene/medical community for again lowering the TLVs and EELs.

Similar methods and instruments are used for both hydrazine and MMH and respond to both. Only a few instruments are capable of discerning between hydrazine and MMH. The following sections are subdivided by active and passive sampling methods. With *active* we understand that the system needs a pump to force air through the apparatus. *Passive* samplers or badges depend on diffusion of ambient air and air movements (often the draft of the working person moving through the working environment). Passive methods have the advantage that they do not require a portable power source, but they are probably not as accurate as active samplers. Other methods of subdividing a chapter on trace analyzers would be by *direct reading* and *not direct reading* instruments.

It is very difficult to maintain a current list of commercially available vapor detection instruments that are suitable for the detection and monitoring of hydrazine, MMH, and UDMH concentrations. Lists of instruments that had been assembled in previous books on hydrazines [460] quickly became obsolete because some manufacturers went out of business, others merged, and a few new ones entered the field. In addition to the need to monitor hydrazines, many test and launch sites had simultaneous requirements to detect and monitor nitrogen dioxide from leaking dinitrogen tetroxide or mixed oxides of nitrogen (MON). Instruments were sought that could detect and separately identify both hydrazine fuels and nitrogen oxide oxidizers. These instruments were generally described as *hypergolic vapor detectors*.

Progress in the area of toxic rocket propellant vapor detection has been significant during the past decades, necessitated by the realization that there is a wide range of potential adverse physiological effects caused by hydrazines. Most of the work performed on propellant vapor detectors in the US was aimed at the detection of the more volatile MMH, which was used in the Space Shuttle OMS/RCS and in the MINUTEMAN and PEACEKEEPER ICBM third stages deployed in missile silos. Only relatively little work has been conducted specifically for the less volatile hydrazine  $\text{N}_2\text{H}_4$ . Surveys of missile propellant vapor detectors have been published in the literature from time to time but quickly became obsolete. A table of summary publications dealing with hypergol vapor detectors that was published in a hydrazine book in 2001 now has only historical value. For a now outdated review of the history of hypergol vapor detection instrument and passive sampler development and testing, see [460]. All information on detectors and samplers is too complex and quickly outdated to be repeated here. The following is only a random sampling of some of the analytical methods used for the detection and quantitation of MMH and other hydrazines. Initially, one will have

to rely on manufacturer's literature to select a system that satisfies the requirements of a given rocket propellant installation, and then verify manufacturer's claims by on-site evaluation under real operating conditions.

Most of the active instruments and passive badges capable of detecting and quantifying MMH vapor in air work equally well for UDMH and hydrazine vapors. Therefore, the information contained here in the MMH chapter will not be repeated in the UDMH chapter.

#### **4.7.13.1 Sampling Methods for Methylhydrazines in Air** **Liquid-Filled Impingers and Wet Chemical Methods**

Two different instruments, Technicon Auto-Analyzer, in which an aerosol captures electrons in a radium source and causes a decrease in electron current, and the Mine Safety Appliances Billion-Aire, which absorbs MMH from a gaseous stream pumped from the exposure chamber into a liquid containing iodine in potassium iodide, which decreases in color after reaction with the MMH, were compared for the continuous analysis of exposure chamber atmospheres [461–463]. The transmittance of the solution was measured continuously in a flow colorimeter and could be related to the concentrations of the MMH. The reaction of iodine with MMH was adapted to the analysis of MMH vapor in air. By adjustment of pH and potassium iodide concentration, stoichiometric reduction of iodine in solution was accomplished. This method permitted the absolute measurement of MMH concentrations in standard bag samples, which were then utilized for calibration of the MSA Billion-Aire analyzer.

#### **Solid Sorbent Tubes**

Measurements at the NASA Kennedy Space Center (KSC) showed that occupational exposure of technicians to hydrazine and MMH vapors was well within tolerable limits even after the lowering of the TLV from 100 to 10 ppb in 1991 [464]. Sampling methods were sensitive enough to measure exposure levels at or below the proposed American Conference of Governmental Industrial Hygienists (ACGIH) TLV of 10 ppb/8 h. The operations monitored included propellant transfer operations, flight hardware processing, and launch vehicle fueling operations that occurred at KSC or the adjacent CCAFS. A similar set of 128 air samples taken and analyzed for hydrazine, MMH, and UDMH at NASA White Sands test facility in 1991 showed that hydrazine or MMH concentration in most work areas was below the proposed TLC of 10 ppb [465]. The air samples were taken by aspirating air through glass tubes filled with USSS No. 30–60 granular sulfuric acid impregnated fire brick at a rate of 1 L/min for 10 min. The sorbent was then leached with buffer solution in an ultrasonic agitator and the solution analyzed by HPLC with electrochemical detection. Several samples were reported as “None detected,” but the detection limit was unfortunately not stated (it is assumed to be below 2 ppb). Parallel tests showed the dubious value of conventional Interscan 4186 measurements, which did not correlate with the absorption tube readings at all.

Instead of air sampling with liquid absorbent dilute acids in impingers (“bubblers”), it is more practical to use solid absorbents, which consist of inert granular ceramic carriers impregnated with acid, held in sampling tubes through which air is drawn at a controlled rate and for a known duration of time. Some of these solid sorbent tubes and the subsequent spectrophotometric analysis capture MMH as well as UDMH [466]. With this particular method, the relative error of measurement was less than 17%, and the recovery rate was better than 80%.

### **Sample Dilution Methods**

Sometimes the concentrations of MMH or NTO to be measured may be higher than the upper range of instruments at hand and the air samples need to be diluted before admitting them to the instrument. An MMH vapor sample-diluter was constructed for 3 to 1 dilution. A 3 to 1 diluter would bring samples containing 500 ppm MMH into the range of the existing instrument [467, 468].

### **Calibration Methods for MMH Analyzers**

All field analyzers have to be brought back to the central laboratory from time to time to be re-calibrated. Calibration is done with vapor generators, which can provide an air stream with a known amount of MMH vapor in it. The reproducible vapor concentrations are usually generated with permeation tubes.

## **4.7.14 Active Analysis Methods for Methylhydrazines in Air**

### **4.7.14.1 Gas Detector Tubes**

The popular Draeger tube for MMH was tested again for accuracy with MMH vapors from a vapor generator that was calibrated with the *p*-dimethylaminobenzaldehyde (PDAB) method on air samples drawn through an impinger with acid [469]. These tubes change color from yellow to blue in the presence of MMH or other base-forming gases (hydrazine, amines, ammonia). At levels of 1 and 2 ppm MMH the results of the tubes averaged within the required  $\pm 20\%$  deviation.

### **4.7.14.2 Paper Tape Analyzers**

A portable detector for mixed-hydrazine propellant fuel (MHF-3) vapors at low concentrations for shipboard use was developed at the Naval Research Laboratory [470]. This active detector consisted of PDAB-impregnated paper and responded to hydrazine or MMH within the range 0.5–10 ppm. PDAB was also the reagent used in an E41 chemical warfare agent alarm modified to fit the needs of the Air Force in monitoring the air for MMH leaks in MINUTEMAN III silos [471]. The same E41 alarm system was also tested as a candidate for use as a shipboard detector on board Condor missile-carrying ships and found to perform reliably for MMH detection [472]. The principle of this test method was to impinge an air stream on a tape impregnated with PDAB. The presence

of hydrazine or MMH resulted in an orange spot. The change in color was observed by a system with a photoelectric cell.

The MDA Autospot Model 3060 and MDA 7100 analyzers, which used the discoloration of paper tape impregnated with phosphomolybdic acid, were evaluated for remote sampling of MMH using an auxiliary pump [473, 474]. One of the first paper tape instruments was the AutoStep hydrazine analyzer made by GMD Systems, Inc., a company that was later absorbed by Bacharach [475]. The GMD MK-2 is a microprocessor-controlled instrument with direct liquid crystal display meter readout and full data storage facilities. Some of the performance requirements established for the detector were: accuracy of plus or minus 1 ppb tested at 10 ppb; linear range of 0 to 400 ppb; zero and span drift of plus or minus 2 ppb in 4 h; response time of less than 4 min to 90% tested at 10 ppb; error due to temperature change from 273 to 313 K (0 to 40 °C) at 45% relative humidity (RH) within  $\pm 20\%$ ; and error due to humidity change from 10 to 80% within  $\pm 25\%$ . Evaluation tests, other than the RH test, were performed using hydrazine, MMH, and UDMH vapors ranging from 1 to 400 ppb at 298 K (25 °C) and 45% RH.

#### 4.7.14.3 Electrochemical Analyzers

The NASA KSC evaluated three different instruments in 1987, including the ESI-7000 (electrochemical), Interscan LD-18 (electrochemical), and the Miran 101 (IR absorption) [476]. At that time, the ESI-7000 was the preferred instrument for continuous area monitoring for MMH and NO<sub>2</sub>. NASA later started development of a second-generation Hypergolic Fuel Vapor Detection System, and a wider range of all known commercially available technologies was considered, including electrochemical, IR, photoionization, and optically scanned chemically treated paper tape [477, 478]. Fifteen instruments were procured, and a preliminary series of tests for basic performance was completed in 1990. Several of the sensors were susceptible to variations in RH, which is typical for the Florida climate.

The Olfactron 6110 analyzer once made by the Control Systems Division of Tele-dyne Inc had separate sensors for NO<sub>2</sub> and hydrazine-type fuels. The Olfactron was calibrated in the laboratory and then field tested for MMH and UDMH at a static rocket test site and its results were compared with cumulative measurements with bindone personal monitor badges [479]. The studies with the Olfactron Model 6110 showed this instrument to be deficient in several respects: **(1)** field calibration with UDMH for MMH detection could not be accomplished as designated by the manufacturer, and **(2)** the reproducibility of the estimation of repeated exposures was limited to short-term events and could not be accepted for operational situations.

#### 4.7.14.4 Infrared-Stimulated Acoustic Microphone Sensors

Methylhydrazine vapor in air can be detected by a high-throughput, all-fiber near-IR spectrometer based on an integrated acousto-optic tunable filter and an erbium-doped fiber amplifier [480]. This tunable filter was based on Bragg interactions

between a waveguide and surface acoustic waves. Advantages included all-fiber construction, smaller size, narrower spectral resolution (1.7 nm), higher diffraction efficiency (37%), and lower rf power requirement (150 mW). A relatively narrow spectral tuning range (about 80 nm) was the only drawback for this integrated tunable filter. However, this disadvantage was overcome by using the filter for measurements in which its tuning range was coincident with the light source and also with absorption bands of analytes. The all-fiber nature, compactness, high throughput and high sensitivity of this spectrophotometer made it particularly suitable for on-line and real-time detection of trace gases in hostile environments, including leak detection of MMH at a limit of detection of 191 ppm.

#### 4.7.14.5 Infrared Diode Lasers as a Radiation Source for Spectrophotometers

The design of a diode laser-based leak detection system operating in the range from 6350 to 6650  $\text{cm}^{-1}$  (1.49 to 1.58  $\mu\text{m}$ ) was based on peak absorption cross-section measurements of MMH, as determined from fixed wavelength absorption measurements recorded at various pressures [172, 173].

#### 4.7.14.6 Thin Film Chemiresistors

Thin film chemiresistors have been tested for the detection of MMH and hydrazine [481]. HypergoLeak [482] is a polymer nanowire-based chemoresistive sensor. The fabricated polymer nanowires have proven capable of detecting hypergolic fuels and oxidizers. The nanowires have been used to detect 10–300 ppm MMH and 10–100 ppm  $\text{NO}_2$ , with the capability to detect lower concentrations. The response of the nanowires correlated well with the analyte concentrations determined by other methods.

#### 4.7.14.7 Gas Chromatographic Methods

The detection of hydrazine type fuel vapors in air has been studied using GC and colorimetric methods that are adaptable to the Army's E41 Chemical Agent Alarm vapor detector. Gas chromatography with a flame ionization detector can detect 1.0 ppm mixed hydrazine fuel-5 (MHF-5) vapor (mostly MMH) and 0.5 ppm UDMH. In parallel, UDMH has been detected by a colorimetric method using phosphomolybdic acid. The E41 alarm using this principle can trigger an alarm to 0.5 ppm UDMH in about 30 s [483].

Methylhydrazine in air can be determined by capillary gas chromatography [484]. The results showed that good linearity can be obtained in range 0–54 mg/L, and the minimum detectable concentration was 0.6 mg/L.

#### 4.7.15 Passive Personal Dosimeter Badges (Direct Reading)

Colorimetric detectors depend on the reaction of MMH vapor with a reagent chemical to produce a colored compound. The reagent is usually deposited on a strip of filter paper or chromatogram sheet. The intensity of the color produced by reaction with

MMH is proportional to the MMH concentration in the contaminated atmosphere and the time of exposure. Similar badges have been developed for hydrazine and UDMH. Several of the badges in use also responded to ammonia and were not specific for one particular hydrazine or alkylhydrazine.

Simple, direct-read monitoring systems for hydrazines (hydrazine, MMH, and UDMH) consist of a badge-type monitor and a color comparator [485]. The badge operates on the principle of diffusion and it indicates the presence of hydrazine(s) by forming a color change. The color change occurs when the targeted vapor diffuses and reacts with a flat indicator layer. The intensity of the color developed is directly proportional to the exposure dose. For quantitative measurement of exposure doses of hydrazines, the intensities of the colors developed are compared with color standards in the color comparators. The minimum detectable limits for hydrazine, MMH, and UDMH are 4.5, 6, and 10 ppb  $\times$  h respectively. Cross interferences of several organic and inorganic substances known as normal satellites of hydrazines, including up to 25 ppm ammonia, were examined. None of the tested substances showed any effect on the performance of the hydrazines' systems. The hydrazine and MMH systems use the same sensor. This sensor is ten times more sensitive to hydrazine and MMH than to UDMH.

#### 4.7.16 Analysis of Trace Contaminants in MMH

Absorption of atmospheric carbon dioxide into hydrazine and formation of carbazic acid have been the cause of numerous corrosion incidents. Similarly, carbon dioxide absorption into MMH and resulting corrosion problems were also the reason for the development of the following gravimetric procedure for the analysis of carbon dioxide and methylcarbazic acid in MMH [351]. In this method a 10-mL sample of MMH in CO<sub>2</sub>-free water is reacted with 10 mL of a barium hydroxide solution prepared by dissolving 10 g of Ba(OH)<sub>2</sub> in 500 mL of CO<sub>2</sub>-free water. The precipitate is filtered through a tared fritted glass filter, washed, dried, and weighed. Because sulfate ion (if it was present as a contaminant) would cause a precipitate as well, the weighed precipitate is then washed with 0.1 N hydrochloric acid, water, dried, and weighed again. The barium carbonate would dissolve in HCl, but barium sulfate would remain in the crucible. It was verified gravimetrically that the precipitate is barium carbonate and not barium methyl carbazate. It was assumed that methylcarbazic acid and MMH methyl carbazate (the form in which dissolved CO<sub>2</sub> exists in MMH) hydrolyze to free carbonate ion under the conditions of this analysis. MMH absorbs carbon dioxide rapidly from the air. Therefore, all sample weighing must be done under CO<sub>2</sub>-free nitrogen. Typical propellant samples contained 25 to 224 ppm CO<sub>2</sub>.

In trying to answer the question if *N*-nitrosodimethylamine detected during disposal of MMH is caused by UDMH contamination in the MMH or is to be expected even from perfectly pure MMH, a very sensitive method was developed for analysis of trace contamination of UDMH in MMH, which involved forming the hydrazones

with adamantanone instead of acetone, followed by capillary GC separation and mass spectrometric identification [486]. The acetone hydrazones of MMH and UDMH were not sufficiently stable for this application, but the adamantanone hydrazone gave better results. The bulk of the adamantanone group prevents enolization and other side reactions, leading to instability of the derivative in the GC at a high temperature. The adamantanone derivatives also contained more carbon and were easier to detect than the acetone hydrazones in a GC with FID. The UDMH derivative, a trace contaminant, eluted prior to the MMH derivative, which was desirable because the larger peak of the MMH derivative may be trailing a bit and would cover (hide) the trace of UDMH. The adamantanone derivatives of UDMH and MMH were sufficiently thermally stable for GC analysis, but decomposed slowly on standing, even in the absence of air or light. The samples should therefore be analyzed within 0.5 and no more than 4 h after derivatization. The GC separation used 15-m capillary columns coated with crosslinked poly(ethylene glycol) or a polysiloxane, and 0.02 to 0.33% UDMH was detected in all propellant-grade MMH samples analyzed at NASA WSTF.

## 5 Properties of Methylhydrazinium(1+) Salts

Methylhydrazine forms salts with strong acids. In aqueous solution with nitric acid only the singly protonated salt, methylhydrazinium(1+) nitrate, MMHN,  $[\text{H}_3\text{CNH}_2\text{-NH}_2]^+[\text{NO}_3]^-$  is formed. If MMHN is dissolved in concentrated nitric acid, the diprotonated salt can be obtained.

### 5.1 Thermal Stability of Alkylhydrazinium Salts

The thermal stability of alkylhydrazinium salts varies over a wide range of temperatures at which onset of exothermic decomposition can be observed. Most alkylhydrazinium salts are potentially explosive and data on thermal stability must be known before these chemicals can be safely stored and transported as dry solids. Even salts that may not necessarily be considered for a particular application such as in a rocket propellant or an explosive are included here, although such applications are frequently the motivation for thermal stability studies. In addition to those salts with oxidizing anions where instability of the salt must be expected, many alkylhydrazinium salts with inert anions decompose exothermically as well. There is still no complete understanding of the effect of the anion on the stability of alkylhydrazinium salts. Methods and instruments for studying thermal stability of hydrazinium salts include DTA, TGA, DSC, ARC, on-line MS of gaseous products, and IR/FTIR spectrophotometry. The same methods are also used to study the thermal stability of alkylhydrazine liquids.

Thermal stability—or rather thermal instability—of alkylhydrazinium salts ranks all the way from a mild endothermic decomposition to a sometimes violently exothermic, in fact explosive or even detonative decomposition.

## 5.2 Properties of Methylhydrazinium(1+) Nitrate

The salt of major concern is methylhydrazinium(1+) nitrate, MMHN,  $\text{H}_3\text{CNHNH}_3\text{NO}_3$ ,  $\text{C}_1\text{H}_7\text{N}_3\text{O}_3$ , CAS RN [29111-69-1],  $M = 109.09 \text{ g/mol} = 9.1667 \text{ mol/kg}$ , which sometimes forms inadvertently from residual bipropellants in NTO/MMH thrusters from the dribble volume after the engine has shut down. Under adverse conditions, the salts formed from uncombusted propellants may accumulate in the engine and explode next time the engine is operated, resulting in severe pressure spikes. The ground test experience using low-thrust attitude control engines has shown a correlation between the pressure spike phenomena and the residue formation. Methylhydrazinium(1+) nitrate melts at 310.6–314.6 K (37.5–40.5 °C) and has a density of  $1.541 \text{ g/cm}^3$ .

### 5.2.1 Infrared Spectra of Methylhydrazinium Nitrate

The MMHN IR spectrum is similar to that of MMH, with the exception of the peak at  $1375 \text{ cm}^{-1}$ , which is due to the nitrate ion [487]. The absorptions between  $3200$  and  $3000 \text{ cm}^{-1}$  and the absence of the strong peaks at  $2800 \text{ cm}^{-1}$  indicate that the proton is attached to the nitrogen atom that already carries the methyl group.

The physical, chemical, and safety properties of MMHN were thoroughly investigated as part of a research program to explain hard start phenomena in hypergolic rocket engines [325, 488, 489]. The work at USBM included the measurement of IR spectra of MMHN, such as the one shown in Figure 30 [490].

**Figure 30:** Infrared spectrum of methylhydrazinium nitrate. (Reproduced and modified from [490].)

Methylhydrazine and  $\text{NO}_2$  were reacted in laboratory vacuum chambers under non-ignition conditions and residues were collected and analyzed [326, 327]. The main constituent of the condensed reaction products was MMHN.

Combustion residues were collected from NTO/MMH engines firing into a vacuum chamber at either steady-state or pulse-mode and the IR spectra were compared with those of MMHN shown in Figure 31 [491].

**Figure 31:** Infrared spectrum of methylhydrazinium nitrate. (Reproduced and modified from [491].)

Exhaust from NTO/MMH thrusters is a potential source of plume contamination for cooled sensor optics on satellites. The effect of MMH nitrate on scatter at  $3.39\text{ }\mu\text{m}$  was investigated as a function of temperature within the range 200–350 K and as a function of thickness [492]. The space-simulated deposition of MMH nitrate took place under high vacuum onto a bare beryllium mirror.

### 5.2.2 Thermodynamic Properties of Methylhydrazinium Nitrate

The heats of combustion of MMHN,  $[(\text{CH}_3)_2\text{H}_2\text{NNH}_2][\text{NO}_3]$  were determined experimentally and calculated thermodynamically [493]. The agreement between the experimental and theoretical values (in parentheses) was satisfactory: 1136 (1090) kJ/mol = 10418 (9996) kJ/kg = 2490 (2389) kcal/kg.

### 5.2.3 Molecular Structure of Methylhydrazinium Nitrate

Methylhydrazinium nitrate forms monoclinic crystals, space group  $P2_1/c$  with the unit cell parameters of  $a = 3.7794(4)\text{ }\text{\AA}$ ,  $b = 11.342(1)\text{ }\text{\AA}$ ,  $c = 11.107(1)\text{ }\text{\AA}$ ,  $\beta = 99.09(1)^\circ$ ,  $V = 470.15(9)\text{ }\text{\AA}^3$ ,  $Z = 4$ , and  $\rho_{\text{XRD}} = 1.5411(3)\text{ g/cm}^3$  [494]. The methylhydrazinium ion has four hydrogen bonds connecting it to neighboring nitrate ions. The terminal  $\text{NH}_2$  nitrogen atom is connected via hydrogen bonding to two nitrate ions, the central

nitrogen atom to a nitrate ion and another methylhydrazinium ion (N—N distance = 2.938(2) Å). The arrangement of methylhydrazinium ions and nitrate ions in the crystal lattice has been illustrated in an ORTEP plot together with bond lengths.

### 5.2.4 Thermal Stability of Methylhydrazinium Nitrate

When heated, MMHN dissociated rapidly and the gaseous dissociation products recombined and deposited on available cold surfaces inside the test apparatus (quartz spring balance). Results of mass loss rate measurements at 298, 328, and 367 K (25, 55, and 94 °C), all at low pressures (30 μm Hg), were as follows: 0, 0.04, and 0.35 mg min<sup>-1</sup> cm<sup>-2</sup>.

When MMHN in the semisolid form of an engine residue was heated at 443 K (170 °C) and under atmospheric pressure conditions, it converted to methylammonium nitrate. In the DTA, a melting endotherm was observed at 314 K and the exotherm peaked at 481 K [487].

Methylhydrazinium and methylammonium nitrate are among the white deposits frequently observed in post-firing NTO–MMH rocket engines as a result of incomplete combustion. Because the nitrates are potentially detonable, additional safety investigations were carried out on their thermal decomposition [491, 495–497]. MMHN has a melting point of 310.6–314.6 K (37.5–40.5 °C) and begins to decompose at 400 K. The thermal decomposition of MMHN at temperatures between 353 and 473 K (80 and 200 °C) produced (in order of abundance): methylamine, water, dinitrogen, NO, NO<sub>2</sub>, CH<sub>4</sub>, NH<sub>3</sub>, CH<sub>3</sub>N<sub>3</sub>, N<sub>2</sub>O, and O<sub>2</sub>. Vacuum DTA with simultaneous on-line mass spectrometric analysis of the decomposition products revealed methylamine, water, nitrogen, nitric oxide, oxygen, and nitromethane among the products. Decomposition was complete at 500 K.

The decomposition of MMH acid salts MMH•HNO<sub>3</sub> and MMH•HCl was studied in their respective 4-M aqueous acid solutions at 345.9 K (72.8 °C) [236]. The chloride salt was perfectly stable over a period of 346 h. In that same period, on the other hand, the nitrate salt decomposed to the extent of 73%. The decomposition products included N<sub>2</sub>, CH<sub>3</sub>NH<sub>2</sub>, NH<sub>3</sub>, and C<sub>2</sub>H<sub>6</sub>. The presence of both N<sub>2</sub> and C<sub>2</sub>H<sub>6</sub> suggests the presence of methyl radicals that could result from the formation of CH<sub>3</sub>N=NH.

Methylhydrazinium nitrate crystals are deliquescent and hygroscopic. Water coordinated to the molecules cannot be removed in vacuum, and heating under vacuum results in decomposition. Longer storage under atmospheric conditions leads to yellow or even brown liquids. The crystal structure of MMHN was determined, the thermal, shock, and friction sensitivity of this compound was investigated, and the products formed during the thermal decomposition were analyzed [494].

Pyrolysis of methylhydrazinium(1+) nitrate was investigated by a confined rapid pyrolysis setup with heating rates on the order of 2000 K/s, coupled to a rapid-scan FTIR spectrometer [498, 499]. Both MMH•HNO<sub>3</sub> and MMH•2HNO<sub>3</sub> started to decompose at about 393 K (120 °C). The nitrates first decompose to release abundant HNO<sub>3</sub>,

which then reacts with the MMH cation to form species such as  $\text{CH}_3\text{ONO}_2$ ,  $\text{CH}_3\text{N}_3$ ,  $\text{HN}_3$ ,  $\text{H}_2\text{O}$ ,  $\text{N}_2\text{O}$ , and small amounts of  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{CH}_4$ , and  $\text{CO}_2$ .

### 5.2.5 Strand Burning of Methylhydrazinium Nitrates

The strand burning rate of methylhydrazinium(2+) nitrate was studied by using a high-pressure strand burner with optical access, coupled with a high-speed camera for capturing and analyzing the combustion characteristics [498, 499]. It was also attempted to study the burn rate of methylhydrazinium(1+) nitrate. However, it was difficult to ignite the methylhydrazinium(1+) nitrate. This is probably for two reasons: **(1)**  $\text{MMH}\cdot\text{HNO}_3$  is a fuel-rich compound; and **(2)**  $\text{MMH}\cdot\text{HNO}_3$  is very hygroscopic. During the preparation process, the  $\text{MMH}\cdot\text{HNO}_3$  strand can absorb enough water from the ambient atmosphere to form a colloidal slurry. The absorbed water makes it difficult to ignite.  $\text{MMH}\cdot 2\text{HNO}_3$  is stoichiometric and its burn rate increased almost linearly from 0.56 mm/s at 0.1 MPa (1 atm) to 14 mm/s at a gauge pressure of 5.5 MPa (gauge) (800 psig). At 6.9 MPa (1000 psi), its burn rate was about 400 mm/s.

### 5.2.6 Detonability of Methylhydrazinium Nitrate

Neat MMHN molten at 318 K and contained in a 25-mm diameter schedule 40 steel pipe underwent a low-velocity detonation (LVD; 2 mm/ $\mu\text{s}$ ) when boosted with 50 g of tetryl and zero gap [500]. In a gap test, molten MMHN exhibited minimum film thicknesses of 1.5 and 1.8 mm for propagation at 2.2 to 2.3 mm/ $\mu\text{s}$ . Mixtures of MMHN and MMH may be found in the residues from leakage or incomplete combustion in rocket engines operating on NTO/MMH. Samples of 90% MMHN and 10% water or 90% MMHN and 10% MMH did not propagate detonation in a wedge test with a wedge taper from 6.2 mm to zero.

In similar tests, it was confirmed that even very concentrated solutions containing 90% MMHN did not sustain detonation in layers as thick as 1.25 cm. The pure molten methylammonium nitrate showed LVD behavior with a detonation velocity of 2200 m/s, and a critical film thickness of 0.03 cm [490].

Methylhydrazinium nitrate showed poor sensitivity toward shock or friction. No impact sensitivity detonation was observed in the drop hammer test (5 kg, 50 cm) [494]. Also, no detonation was observed when grinding the compounds in a mortar. MMHN was insensitive to an electric discharge of about 20 kV. Fast heating with a Bunsen burner resulted in melting and at higher temperatures in a vigorous decomposition under gas evolution. Slow heating gave a slow decomposition at temperatures higher than 333 K (60 °C).

### 5.2.7 Toxicity of Methylhydrazinium Nitrate

Technicians who are servicing post-flight NTO/MMH thrusters without protecting themselves with gloves may accidentally absorb MMHN through the skin. Dermal

exposure tests with rats and hamsters have shown that MMHN is readily absorbed through the skin and that the topical LD50 of MMHN is similar to that of MMH [501, 502]. In a study of the effects of MMHN on mitochondrial function of rat hepatocytes, MMHN and other hydrazinium nitrates decreased the mitochondrial function in a dose-dependent manner [503]. Toxicity data for MMHN are summarized in Table 47 [504].

### 5.3 Properties of Methylhydrazinium(1+) Azide

Methylhydrazinium(1+) azide crystals melt at 341 K (68 °C). In the DSC there was a melting endotherm peak at 342.4 K (69.3 °C) and another weak endotherm at 424.6 K (151.5 °C). Methylhydrazinium(1+) azide crystals are orthorhombic, space group *Pnma* with unit cell parameters of  $a = 9.962(1) \text{ \AA}$ ,  $b = 5.1316(5) \text{ \AA}$ ,  $c = 9.2280(9) \text{ \AA}$ ,  $\alpha = 90^\circ$ ,  $V = 471.77(9) \text{ \AA}^3$ ,  $Z = 8$ , and  $\rho_{\text{XRD}} = 1.2545(2) \text{ g/cm}^3$ . The hydrogen-bonded methylhydrazinium and azide ions form layers. The methyl groups of the methylhydrazinium ions are above and below these layers, so that two methyl groups are between each layer [505, 506]. Similar tests were performed for dimethylhydrazinium azide [507].

Methylhydrazinium(1+) azide showed almost no sensitivity toward shock or friction. No detonation was observed after dropping a weight of 5 kg from 50 cm onto this compound, nor was any detonation observed when grinding the compound in a mortar.

### 5.4 Properties of Methylhydrazinium(1+) Nitroformate

Methylhydrazinium nitroformate crystals were prepared and characterized by XRD, NMR, Raman, and IR spectroscopy along with five other nitroformate salts of aliphatic amines [508].

## 6 Combustion of MMH

Methylhydrazine is a monopropellant and a fuel. MMH monopropellant decomposition can be characterized by measuring strand burning rates of liquid MMH in a quartz capillary or in a consumable straw. There are numerous strand burning rate measurements on hydrazine, and similar ones, but not as many, strand burning rate measurements have been made on MMH and even on UDMH. In addition, burning rates of strands or droplets of MMH in oxidizing atmospheres needed to be measured.

## 6.1 MMH Flames in Oxidizing Atmospheres

In analogy with the study on self-heating and spontaneous heating of hydrazine [509], the self-heating and spontaneous ignition in the combustion of MMH in oxygen were examined [510]. The combustion according to:

is exothermic with  $-1340 \text{ kJ/mol}$  ( $-320 \text{ kcal/mol}$ ). The critical conditions of pressure, temperature, diluents, and oxidizer–fuel ratio were examined in this investigation. Uncommon among gas-phase reactions, the combustion of MMH is dominated by thermal effects, and no obvious symptoms of radical chain branching could be detected. The technique used by Gray consisted of premixing MMH and oxygen at ambient temperature and admitting it to a heated, evacuated vessel while simultaneously recording temperature and pressure until ignition occurred. A thermocouple in the center of the vessel would frequently read temperatures higher than the wall temperature before ignition occurred, indicating a self-heating mechanism preceding actual ignition. An activation energy for the  $\text{O}_2/\text{MMH}$  reaction was derived from the slope of a  $\ln(P_c/T_a^2)$  versus  $1/T_a$  curve, where  $P_c$  is the critical pressure at which ignition occurs and  $T_a$  is the initial temperature of the Pyrex vessel. The calculated activation energy was  $80 \text{ kJ/mol}$  ( $19.1 \text{ kcal/mol}$ ), which compared well with  $101 \text{ kJ/mol}$  for hydrazine itself and  $67.3 \text{ kJ/mol}$  for UDMH.

## 6.2 Droplet Burning of MMH in Oxidizing Atmospheres

The burning of MMH droplets in an  $\text{NO}_2$  atmosphere is the key mechanism for hypergolic rocket engines with NTO/MMH. The application of this rocket propellant combination and the ignition delay of impinging liquid NTO and liquid MMH will be discussed in future volumes on hypergolic bipropellant combinations.

The burning of MMH and UDMH droplets in oxidizing atmospheres (other than  $\text{NO}_2$ ) was studied as a means of separating the monopropellant decomposition and oxidizer-supported flames of MMH or UDMH combustion, and also in comparison with hydrazine [511–513]. The flat-flame burner could be fed with lean fuel mixtures, generating oxygen-rich hot gases in which secondary combustion of the droplet vapor decomposition products would take place. The conditions included  $1660\text{--}2530 \text{ K}$  at ambient pressure. The tests used single droplets suspended from a quartz filament measuring  $100 \mu\text{m}$  in diameter as well as porous Alundum spheres. Droplet diameter could thus be varied from  $0.11$  to  $1.91 \text{ cm}$ . The fuel droplets were burned in the hot gaseous combustion products of a flat-flame burner to simulate rocket engine operating conditions. The flat-flame burner could be fed with lean fuel mixtures, generating oxygen-rich hot gases in which secondary combustion of the droplet vapor decom-

position products would take place. The conditions included 1660–2530 K at ambient pressure. Decomposition flames were not luminous at all, but oxidation flames of all three fuels showed two separate distinct zones of luminosity.

Whereas the results of the hybrid model and a bipropellant evaporation model were quite different for hydrazine, the distinction was not as pronounced for MMH or UDMH. In the hybrid mode, the monopropellant decomposition of the fuel prior to combustion was taken into consideration. The results indicated that fuels capable of hybrid combustion showed increasing burning rate with increasing ambient oxygen concentration (Figure 32), diameter, and ambient temperature. Similar graphs for hydrazine instead of MMH have already been shown in this publication, the *Encyclopedia of Liquid Fuels*, chapter “Hydrazine.”

Comparing the hydrazine and MMH decomposition rates, it is obvious that MMH monopropellant droplet burning proceeds more slowly than that of hydrazine in spite of the higher volatility of MMH and increased luminosity of MMH decomposition flames.

**Figure 32:** Methylhydrazine droplet mass burning rate at various oxygen concentrations. (Reproduced and modified from [22] as adapted from [511].)

Methylhydrazine droplet burning in  $N_2O_4$  atmospheres was studied over a wide range of pressures and Reynolds numbers to simulate processes near the injector plane inside a bipropellant rocket engine [514]. The oxidizer droplet adjacent to the fuel droplet substantially influenced the flame configuration and the vaporization rate of the fuel droplet. At low Reynolds numbers ( $N_{Re} < 20$ ) the fuel droplet vaporization rate increased due to either a leading or a trailing oxidizer droplet. At high  $N_{Re}$ , the fuel droplet evaporation rate was not much influenced by the proximity of an oxidizer droplet. Multiple flame configurations and vaporization rates characteristic of temperature-sensitive, high activation energy Arrhenius kinetics, which occurred under certain flow conditions for *n*-octane droplets burning in air, were not exhibited by the NTO/MMH hypergolic propellants, which were characterized by a low activation energy of reaction.

In a study of the evaporation of MMH droplets at high pressure, the MMH droplet radius and temperature at different environmental pressure was computed and compared with experimental results [95]. The rate of evaporation, the heat transfer coefficient, and the mass transfer coefficient were considered and computed and they agreed well with the test data. The effect of the Lewis number on the limit pressure of evaporation was evaluated and it showed that the evaporation model and the computational method were correct. This method may be used to evaluate the evaporation of other fuels.

### 6.3 MMH Flames in Oxidizing Atmospheres

The hypergolic ignition and combustion of MMH in rocket engines will be presented in a future *Encyclopedia of Hypergolic Bipropellant Combinations*.

#### 6.3.1 MMH Flames in Nitrogen Dioxide Atmospheres

If both oxidizer and fuel tanks of an NTO/MMH propulsion system leak and form separate puddles on the ground, ignition will occur at the boundary of the two puddles. Because  $N_2O_4$  evaporates faster than MMH, the atmosphere in the vicinity of this mishap will be  $NO_2$ -rich and hover over the liquid MMH pool. An experimental study of an NTO/MMH counterflow pool flame was conducted to obtain data that had to be matched to proposed detailed chemical reaction mechanisms [515]. The flames were observed and videotaped through high-speed imaging of chemiluminescence of broad-band light emission with Band Pass Filters centered at  $310 \pm 5$  nm and  $430 \pm 5$  nm. One-dimensional numerical simulations with detailed chemical kinetics were performed to help explain the flame structures observed in the experiment, considering, along with the proposed reaction mechanisms, the MMH puddle evaporation environment at the boundary conditions. The experimental results showed a multi-layered flame structure of an NTO/MMH non-premixed flame composed of two orange

flames and one weak blue/white flame. Results obtained in numerical simulations indicated that NTO/MMH forms the multi-layered flame structures of two orange flames owing to  $\text{NH}_3$  decomposition and  $\text{NO}_2$  recombination, and the blue/white flame was in the region between the two orange flames.

## 7 Handling of MMH

Because of the toxic and corrosive properties of hydrazines including MMH and UDMH, these compounds should not be handled in the literal sense of the word, that is, with bare hands or in intimate contact with the skin. The toxic and corrosive properties of hydrazines make it mandatory that precautions necessary for safe handling be sufficiently understood. Once the proper precautions for storage and transfer of hydrazines have been taken, hydrazines can be handled as safely as any other hazardous chemicals. Adequate operator training in propellant loading will prevent future accidents. It is the objective of this chapter to provide the MMH user with at least the most important information to get the job done safely and successfully.

The main application for MMH is in space propulsion. Space propulsion system hazards for hydrazines and other rocket propellants are summarized in the *Space Propulsion Hazards Manual* [516–518], a three-volume series useful for the planning of ground-service equipment and fueling operations. It was even intended to convert this paper manual to a CD-ROM with hypertext crosslinks.

Hypergolic propellants, NTO and MMH, can be handled safely if propellant loading personnel is properly trained. A 2-day training course for the safe handling of hypergols was developed and used for training purposes at NASA [519]. The design of hypergolic propellant ground service equipment for fueling launch vehicles and satellites at NASA KSC is outlined in [520].

### 7.1 Storage, Transportation, and Disposal of MMH

Storage facilities for MMH are needed at the point of production, as a method of government stockpiling of strategically important fuels, logistics at the point of consumption to assure against interruptions of supply, and finally, for the storage of waste propellant waiting to be reprocessed or destroyed.

#### 7.1.1 Storage Compatibility Requirements and Setback Requirements for Liquid Propellants

Quantity-distance regulations set forth in the US Army Safety Manual [521] first categorize all propellants into four hazard groups I through IV, then assign six storage com-

patibility groups A through F. Hydrazine, MMH, UDMH, Ae-50, and mixed amine fuels have been classified in Hazard Group III and Storage Compatibility Group C. A 200-kg (440-lb) drum of MMH in unprotected storage requires a setback of 180 m (600 ft) from inhabited buildings, public traffic routes, and other storage structures containing incompatible propellants. If the drum is in a protected bunker, the setback requirement is reduced to 39 m (130 ft). For ten drums of MMH, the unprotected setback is still the same, 180 m, but the protected setback is increased to 63 m (210 ft).

### 7.1.2 Reportable Quantities for Storage of MMH under SARA Title III

The presence of Extremely Hazardous Substances in quantities in excess of the Threshold Planning Quantity (TPQ) in the vicinity of inhabited areas requires certain emergency planning activities to be conducted. A consolidated list of chemicals subject to reporting requirements under Title III of the Superfund Amendments and Reauthorization Act of 1986 (SARA), also known as the Emergency Planning and Community Right-to-Know Act (EPCRA), and chemicals listed under section 112<sup>®</sup> of Title III of the Clean Air Act of 1990 was posted on an Environmental Protection Agency (EPA) web site for distribution and downloading in November 1998. This “Mother of all Lists” has been prepared to help firms handling chemicals to determine whether they need to submit reports under sections 302, 304, or 313 of SARA Title III (EPCRA) and, for a specific chemical, what reports may need to be submitted. Releases of Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) hazardous substances, in quantities equal to or greater than their reportable quantity (RQ), are subject to reporting to the National Response Center under CERCLA. Such releases are also subject to state and local reporting under section 304 of SARA Title III (EPCRA). The provisions of the Act are found at 40 CFR Parts 350 through 372. SARA Title III has two distinct goals: to encourage and support advance emergency planning for responding to chemical accidents, and to provide local governments and the public with information about possible chemical hazards in their communities. The TPQs for various hydrazines are summarized in Table 38 and 39.

**Table 38:** Threshold planning quantity of hydrazines.

| CAS RN   | Chemical name     | Reportable quantity (pounds) | Threshold planning quantity (pounds) |
|----------|-------------------|------------------------------|--------------------------------------|
| 302-01-2 | Hydrazine         | 1                            | 1000                                 |
| 60-34-4  | Methylhydrazine   | 10                           | 500                                  |
| 57-14-7  | Dimethylhydrazine | 10                           | 1000                                 |

CAS RN = Chemical Abstracts Service Registry Number

Data source: [522]

**Table 39:** Hydrazines in the consolidated list of chemicals subject to emergency planning.

| CAS RN   | Chemical name         | Quantity, lb       |        |           |               | RCRA CODE |
|----------|-----------------------|--------------------|--------|-----------|---------------|-----------|
|          |                       | Sec. 302 (EHS) TPQ | EHS RQ | CERCLA RQ | CAA 112(r) TQ |           |
| 57-14-7  | 1,1-Dimethylhydrazine | 1000               | 10     | 10        | 15000         | U098      |
| 60-34-4  | Methylhydrazine       | 500                | 10     | 10        | 15000         | P068      |
| 302-01-2 | Hydrazine             | 1000               | 1      | 1         | 15000         | U133      |

CAS RN = Chemical Abstracts Service Registry Number, EHS = extremely hazardous substance, RQ = reportable quantity, TPQ = threshold planning quantity, CAA = Clean Air Act, TQ = threshold quantity, RCRA = Resource Conservation and Recovery Act

## 7.2 Transportation Regulations for MMH

This section is only an incomplete summary of regulations and recommendations affecting the storage and the transfer of hydrazines. Regulations change daily and the hazardous materials coordinator for a chemical company or rocket test site will need to follow updates on a day-to-day basis. This is a full-time job.

The transportation of hydrazines in interstate commerce must comply with the Code of Federal Regulations CFR 49, § 172.101. According to the 1987 revision of that document, MMH was then classified as a **Flammable Liquid** and **Poison**. Because regulations change frequently, it is advisable to check the most recent revision for the applicable requirements before shipping any hydrazines. For transportation, MMH is in Hazard Class 6.1 and has the UN number 1244. The RQ is 10 kg.

## 7.3 Off-Loading of MMH from Spacecraft

Occasionally, it becomes necessary to off-load (de-tank) propellants from a fueled satellite or space probe because the launch date has been postponed or because repair work on a damaged spacecraft cannot be conducted in proximity to loaded propellants.

Off-loading has become necessary for the European GALILEO (MMH and NTO), ARTEMIS (MMH) and ROSETTA (MMH). Note: ARTEMIS was ESA's first GEO data relay communication satellite. Not to be confused with the US planned crewed mission revisiting the Moon, also called Artemis. All spacecraft in this category used bipropellant systems and tanks with surface tension propellant management devices (PMDs). In most cases only the fuel was removed and the oxidizer was left in the tanks, because

its removal or depressurization might introduce gas bubbles into the capillary gallery or the bubble traps and cause loss of NO from MON. Also, evaporation of NTO or MON leaves behind a thin film of nitric acid that would make the corrosion environment even worse than in NTO. There are no generally accepted guidelines for off-loading of propellants from spacecraft, so the personnel in charge of the operations had to develop their own procedures. Some spacecraft do not even have a drain at the lowest point in the system that allows all liquid to be drained by gravity. Other line plumbing systems may have check valves that allow liquid to flow only in one direction, into the tank, and not out of the tank. Most plumbing schematics have dead-ended passages where propellants pool and cannot be removed by flushing.

In the case of ROSETTA, the cancellation of the ROSETTA launch to Comet Wirtanen in 2003 left the spacecraft fully fueled but with no target launch date [524]. While a new mission scenario was being devised it was necessary to make the spacecraft as safe as possible to carry out essential work on the payload and subsystems. It was required to offload all of the MMH fuel to minimize the explosive potential of the spacecraft. In addition, a reduction of the MMH vapors remaining in the spacecraft tanks to a maximum of 1200 ppm was required. Fortunately, MMH is more volatile than hydrazine and MMH is easier to remove than hydrazine. There was no need to unload the MON oxidizer, but a method was proposed to inert the oxidizer tank if the need should arise for an unforeseen reason.

## 7.4 Evaporation and Atmospheric Dispersion of MMH Spills

Chapter “Hydrazine” in *Encyclopedia of Liquid Fuels* contains a fairly detailed summary of studies and computer models for predicting the rate of evaporation and atmospheric dispersion of MMH spills, in addition to similar studies for hydrazine itself, UDMH, Ae-50, and NTO. Only a few of these models include degradation of MMH vapors by autoxidation, photolysis, or adsorption on aerosol particles in the air.

## 7.5 Spill Neutralization of MMH Spills

In spite of all care devoted to planning and conducting storage and transfer of hydrazines, occasional spills may occur. Transfer personnel should be well trained in the containment and neutralization of hydrazine spills. Disposal and spill cleanup of hydrazine(s) fuels has been practiced for many decades and there is a good database on available methods for safe handling of these propellants, for instance chapter 2 in [525].

The most frequently used spill neutralization agent for small spills of hydrazines is liquid chlorine bleach, which is available in most households. In the more storable solid form, hypochlorite is available as calcium hypochlorite (HTH<sup>®</sup>) as a swimming

pool disinfectant. In the experiments with MMH or UDMH and hypochlorite, GC-MS and GC-FTIR analysis of the reaction mixture revealed numerous reaction products that might also be poisonous [526–529]. Bioremediation of MMH spills in high concentrations may not be possible owing to the toxicity of MMH to bacteria in the water and in the soil (see Section 11.12).

Covering up a propellant spill with a layer of foam will not neutralize it, but it will prevent or retard vaporization for a limited time while plans for more permanent neutralization of the propellant spill are being made and equipment for remote manipulation of the spill is put in place. High expansion foams can both quench fires and form a temporary but sufficiently durable barrier to limit the concentrations of vapors from spilled combustible and/or toxic liquids to acceptable levels. Spills of MMH in cargo holds or other closed spaces on ships require special precautions during decontamination to prevent the formation of flammable vapors [530].

## 7.6 MMH Leaks and Leak Detection

Methylhydrazine leaks in propellant storage areas could be detected with the same color-changing indicator paint that has also been tested with UDMH and NTO. Indicating paints irreversibly change color at the point where the leakage occurred [531, 532]. They can be used for detection of NTO as well as UDMH, Aerozine-50, MMH, or hydrazine.

Methylhydrazine or other propellants leaking into vacuum are going to cool by evaporation down to the triple-point temperature and liquid droplets soon freeze and turn into MMH snow. This condition was simulated by spraying liquid MMH into a vacuum chamber with visual (video camera) observation [533].

An all-optical leak detector incorporates a self-referenced, fiber-optics-based sensor platform for detecting MMH at ambient temperatures from 227 to 344 K (–46 to +71°C) [534]. This leak detector can be calibrated to detect leaks in the parts-per-million to parts-per-billion range in air. An optical sensor system can be networked to monitor multiple locations and in real time. An organically modified silicate (Ormocil) matrix was used to develop an optical leak detector for MMH.

## 7.7 MMH Venting to Vacuum and Inerting of Upper Stages

Explosions and fragmentations of spent upper stages or decommissioned satellites in space have been blamed on residual propellants and have created clouds of orbital debris. International space policies now require that upper stages and satellites be emptied of all residual propellants and be passivated (=inerted) at end-of-life.

A numerical study has been performed to evaluate the ARIANE 5 third-stage inerting by the separate venting of MMH and NTO third-stage tanks to vacuum after the

deployment of payloads and prior to re-entry. Two-dimensional viscous flow calculations have been performed through the venting nozzles, and two-dimensional simulations were used from the nozzle exit conditions to determine the plume characteristics [535, 536]. The flow rate decay with decreasing feed pressure was analyzed, and correlations were proposed to describe the plume spatial and temporal distribution. The solid-liquid-vapor phase diagrams of MMH and NTO were required for the analysis, and equilibrium phase changes were examined. It was concluded that the gaseous species produced by the venting process will not condense on surfaces warmer than 250 K. The phase change assessment requires further non-equilibrium condensation analysis, with experimental validation.

## 7.8 Vapor Scrubbers for MMH Fumes

Venting a supply tank after transferring MMH by pressurized transfer from one tank to another releases pressurant gas saturated with MMH vapors that need to be neutralized before they can be released to the atmosphere in the proximity of operators. The fumes have to be passed through scrubbers with sprays or bubble caps of a liquid absorbent or through cartridges with expendable solid sorbents similar to a gas mask canister. Liquid sorbent scrubbers are for stationary large installations where the liquid is recirculated with pumps. Solid sorbents are for small, portable applications. Plain water would absorb some of the MMH, but adding a non-volatile acid to the water spray makes it more effective. Absorbents that have been proposed or proven for removal of hydrazine vapors (as described in *Encyclopedia of Liquid Fuels*, chapter “Hydrazine”) may work equally well with MMH.

### 7.8.1 Vapor Scrubbers for MMH Fumes Using Liquid Absorbents

If only water is used as the scrubber liquid for removal of MMH vapors from vented pressurant gas, the efficiency of the scrubber and the vapor–liquid equilibrium is governed by Henry’s law. The Henry’s law constants have to be known to design a scrubber and determine how many stages are required to achieve satisfactory absorption of hydrazine(s) vapors contained in the pressurant gas of propellant tanks [537]. During the early 1980s NASA KSC initially used bubble-cap scrubber towers 0.5 m wide and 6 m high with 18 plates to absorb propellant vapors from gases vented from MMH servicing equipment into water [538]. Each plate carried 16 bubble caps, typical for chemical industry absorption towers. The propellant vapor was washed with water and the MMH-laden water was subsequently treated with hypochlorite in a separate installation. The scrubber was tested with gases containing 100 ppm hydrazine, 150 ppm MMH, 45000 ppm MMH, or 110000 ppm UDMH, and the effectiveness of the scrubber was verified by sampling the off-gas with Dräger tubes. Numerous alternative reagents have been proposed for hydrazine or MMH

removal. The scrubber system was later converted to operate on citric acid solutions instead of plain water. The bubble-cap scrubber was later replaced by a portable, skid-mounted  $1.8 \times 1.8 \times 3$  m system containing four vertical columns packed with Raschig rings. The four columns drained by gravity into a common 2800-L scrubber liquor tank located beneath the towers. The gas flowed through each of the four towers in series. Development tests were performed with 50000 to 200000 ppm MMH in the inlet gas [539]. The outlet MMH concentrations ranged from 0.3 to 1 ppm MMH, which was considered acceptable at that time. At the KSC, NASA disposes of the MMH-contaminated scrubber liquor through incineration. As an alternative, MMH in the solution can be destroyed by chlorination, but some of the citric acid will be destroyed as well, producing undesirable chlorinated hydrocarbons.

Fourteen percent aqueous citric acid solutions have been used with good success for hypergol vapor scrubbers, but sometimes mold grows on the citric acid solutions in storage while they are not in use. A biocide may have to be added to keep mold from growing. For disposal, the MMH-saturated citric acid solution, which still has to be treated as hazardous waste, is usually incinerated in a flare stack.

Hypergolic fuel and oxidizer scrubbers were examined to determine pass-through emissions produced during actual hypergol transfers [540]. Scrubber liquor used in the fuel scrubber was 14% citric acid solution and the scrubber liquor in the oxidizer scrubber was 5% NaOH + 12% Na<sub>2</sub>SO<sub>3</sub> solution.

Methylhydrazine vapor can be removed with 99.9% efficiency using scrubbers containing acetylacetone solutions as scrubbing liquors [541]. The acetylacetone converts MMH to a non-toxic heterocyclic compound. This approach may reduce the cost of scrubbers that otherwise have to be constructed from corrosion-resistant stainless steel to resist corrosive oxidizing agents previously used in destroying the residual MMH, and in addition it makes the exhausted scrubbing solution easily disposable.

$\alpha$ -Ketoglutaric acid (= 2-ketoglutaric acid, AKGA, HOOCCH<sub>2</sub>CH<sub>2</sub>C(O)COOH), a water-soluble solid, has been proposed for hydrazine or MMH vapor absorption from air or for decontamination of hydrazine- or MMH-contaminated rocket propulsion systems [542, 543]. The reaction of  $\alpha$ -ketoglutaric acid with hydrazine or MMH forms a non-volatile, non-toxic heterocyclic pyrimidine compound. A critical review of the patent claims and preliminary laboratory tests with  $\alpha$ -ketoglutaric acid for hydrazine or MMH vapor absorption or decontamination of hydrazine- or MMH-contaminated rocket propulsion systems concluded that the uncertainties of the completeness of the reaction and lack of complete identification of all reaction products prevented the practical application of this chemical under real-life rocket launch site ground service equipment conditions [544]. When reacting 0.73-M  $\alpha$ -ketoglutaric acid (AKGA) solutions in bench-top lab tests, a solid formed with hydrazine but not with MMH. In more dilute 0.2-M AKGA solutions no precipitate formed with either hydrazine or MMH. Another keto compound tested in hydrazine or MMH scrubber liquids was ethyl acetoacetate H<sub>3</sub>C—C(O)—CH<sub>2</sub>—C(O)—O—CH<sub>2</sub>CH<sub>3</sub> but its reaction with hydrazine or MMH produced a gummy, sticky substance

(a carbinolamine intermediate converting to 3-methylpyrazol-5-one) which clung to the walls and was difficult to remove.

### 7.8.2 Comparison of MMH Scrubber and Disposal Methods

The various organizations using hydrazine and hydrazine fuels are searching for improved ways to minimize vapor hazards during transfer and drum/tank car cleanup by installing propellant vapor scrubbers. The KSC has installed hypergolic vapor scrubbers for some of the fuel-handling operations [537, 540]. Vapor flow rates of 0.28–11 m<sup>3</sup>/min. and equilibrium vapor pressures from fuels up to 310 K (100 °F) warm must be considered. KSC vent stacks are 15 cm in diameter and 11 m tall. An engineering study considered and compared incineration, carbon adsorption, and condensing and refrigeration as alternatives to the scrubber design that served as a baseline. An alternative to direct flame incineration is catalytic incineration. The higher initial investment for platinum or rhenium catalysts might be compensated for by fuel savings in the long run because catalytic incinerators operate at a much lower temperature. Energy requirements for refrigeration as a means of vapor emission control would be excessive, and refrigeration is not an effective method for vapor control.

A LN<sub>2</sub>-cooled cryogenic cold trap was evaluated for the removal of MMH vapor from pressurant gases vented from fuel tanks following static tests or fueling of space vehicles [545]. Scrubbers (either bubbling impingers or trickle bed or bubble-cap counter-current designs) sometimes lack the efficiency for the complete removal of MMH or N<sub>2</sub>O<sub>4</sub>.

Four scrubbers of the S70-1094 type were in operation at NASA KSC launch pads and the Hypergolic Maintenance Facility [546]. These units were designed and built by Martin Marietta Corp., Denver. Each unit measured 2 × 2.4 × 3.3 m (6.5 × 8 × 11 ft) and weighed 2724 kg (6000 lb) dry and 3360 kg (7400 lb) wet. A 15% citric acid solution was recirculated by 100-gal/min. pumps and sprayed into a packed bed trickle bed absorption tower of 0.76-m (30-in) diameter and 2.1 m (7 ft) tall. The contaminated gas flow (up to 3.14 L/s = 400 scfm) passed through two beds in series. The first bed (1.2 m = 4 ft high) absorbed 99.5% of the MMH entering the unit. The second stage improved that removal by another 0.1–0.2% (absolute).

The MMH content of near-exhausted scrubber liquid from citric acid-filled scrubbers can be monitored using coulometric analysis [411]. The same method was also used to analyze gas samples collected with 0.1-N sulfuric acid-filled impingers in the exhaust stack of gases leaving the scrubber in order to verify 100% removal efficiency of the scrubbers.

Hypergolic fuels and oxidizer pressurant gases are (were) vented during fueling and deservicing of the Space Shuttle and other spacecraft and cleansed of toxic propellant vapors before being allowed to vent to the environment. The scrubbers are not 100% efficient and traces of propellant vapors pass through the apparatus. Scrubber emissions are difficult to measure owing to the intermittent purge flow and to the

presence of suspended scrubber liquor droplets. An alternative method of emissions monitoring was introduced [547, 548]. It was suggested that emissions can be determined from field scrubbers without direct measurement of vent flow rates and escaped hypergol vapor concentrations. This alternative approach was based on the scrubber efficiency, which was previously measured during normal steady-state operations, and on the accumulated weight of hypergol captured in the scrubber liquor, which is part of the routine monitoring data of scrubber liquors. The emissions from scrubbers can be calculated by measuring the buildup of hypergol propellant in the liquor, and then using the appropriate efficiency to calculate the fugitive emissions. An estimate of the total emissions from 16 scrubbers at NASA KSC over a period of 3 years indicated that 0.3 kg/year of fuel (MMH and hydrazine) and 234 kg/year of nitrogen dioxide were emitted [549, 550].

### 7.8.3 Vapor Scrubbers for MMH Fumes Using Solid Absorbents

Vapor-absorbent canisters widely in use for servicing F-16 Emergency Power Units (EPUs) with H-70 fuel can potentially be used for MMH absorption as well. The canisters contain potassium permanganate deposited on a granular material. A window reveals a color change when the cartridge is exhausted. F-16 fighter maintenance is done at many air bases all over the world. Pressurant gas from spent F-16 EPUs containing H-70 blend is usually vented through a 7.5-L (2-gal) stainless steel bucket containing 3.8 L (1 gal) of ordinary chlorine bleach (5% NaOCl). As an alternative, a transparent cartridge containing a dry chemical (100 g of alumina granules impregnated with potassium permanganate  $\text{KMnO}_4$ ) has been tested [539]. The  $\text{KMnO}_4$  undergoes a highly visible color change from purple to brown as the result of hydrazine or MMH absorption. The cartridge requires secondary treatment before being disposed of safely.

A candidate scrubber medium, AKGA, a solid adsorbed onto a silica-based substrate was examined as a potential alternative to the hydrazine-family hypergolic fuel neutralization techniques utilized at NASA KSC [551]. Earlier patents indicated that AKGA will react with hydrazines to produce non-hazardous, possibly biodegradable products. The use of AKGA aqueous solutions was demonstrated as a replacement neutralizing agent for citric acid, which was used as a scrubbing agent in liquid scrubbers at NASA KSC. Specific properties of the adsorbent examined include reaction efficiency, the loading capacity of AKGA onto various silica substrates, and the comparison of AKGA media performance with that of the citric acid vapor scrubber systems at KSC and a commercial vapor scrubber medium. Preliminary investigations showed hydrophobic aerogel particles to be a suitable substrate for the deposition of AKGA. AKGA-Aerogel absorbent was more efficient and cost effective than commercially available fixed bed scrubber media, although much less cost effective than liquid-based citric acid stationary or semi-portable, skid-mounted scrubbers (although possibly safer and less labor intensive). A comparison of all three alternative scrubber technologies (liquid AKGA, solid-phase AKGA, and

commercially available sorbent materials) was made considering both hypergol vapor neutralization capabilities and relative costs, compared with the citric acid scrubbing technology in use at NASA-KSC. A critical review of the patent claims and preliminary laboratory tests with AKGA for hydrazine or MMH vapor absorption or decontamination of hydrazine- or MMH-contaminated rocket propulsion systems concluded that the uncertainties of the completeness of the reaction and lack of complete identification of all reaction products has so far prevented the practical application of this chemical under real-life rocket launch site ground service equipment conditions [544].

For propellant vapors vented from propellant tanks in space, the liquid scrubber approach is not feasible. Solid sorbents or cryo traps have to be used to neutralize and immobilize vapors from propellant transfer operations in orbit. Refueling of satellites in orbit with storable propellants involves venting part or all of the displaced gas from the tank being refilled during the filling operation. Pressurant gas from the source propellant tanks has to be vented on completion of the operation. This gas will be saturated with propellant vapor, and it may also have significant amounts of entrained fine droplets (mist) of propellant. Various possible ways of neutralizing vented MMH and NTO propellants were examined [552]. The mass of propellant vented in a typical refueling operation can be in the range of 0.2–5% of the tank capacity, depending on vapor pressure of the propellant, tank temperature, and ullage volume. Four potential neutralization schemes were examined, including chemical decomposition, chemical reaction, condensation, and adsorption. Chemical decomposition to essentially inert materials is thermodynamically feasible for both MMH and  $N_2O_4$  and would be the simplest and easiest neutralization method to implement. Chemical decomposition would require more complex control. Condensation would require a cryogenic refrigeration system and a very efficient cold trap/phase separator. Adsorption systems are much heavier, which is a severe penalty for every kilogram of mass that has to be lifted into orbit.

It has been proposed to add an absorption tower packed with granular activated alumina downstream of the scrubber outlet to securely remove all traces of propellant vapors from the contaminant-laden gases that are vented from a pressurized tank [553]. For MMH, the gases would first be bubbled through 10% sulfuric acid to remove the bulk of the MMH and then cleaned up in the alumina bed. It was not planned to reuse the alumina as regeneration may be more expensive than obtaining new material. The hazardous waste category of the spent alumina had not been established.

## 7.9 MMH Wastewater Decontamination

There are many wastewater treatment methods for hydrazine- and UDMH-containing wastewaters that can be applied equally well to MMH-containing wastewaters.

### 7.9.1 MMH Wastewater Decontamination by UV/Ozone Treatment

One of the more effective treatment methods is a combination of ozone and UV illumination. Ozonation products of wastewater containing hydrazine and hydrazine-related rocket fuels were characterized [554, 555]. Minor amounts of nitrate were produced from the ozonation (synonyms: ozonization, ozonolysis) of hydrazine, MMH, and UDMH. This was probably a result of ammonia or nitrosamine oxidation. MMH ozonation produced methanol and several other peaks, probably formaldehyde, formic acid, and formaldehyde monomethylhydrazone.

The rate of hydrazine destruction by UV ozonation is greatest at a pH of 9.1. The improvement attributable to UV illumination was small for hydrazine itself, but significant for the methylhydrazines. One of the oxidation products observed was methanol. The oxidation of MMH and UDMH by ozone alone is not complete but leads to organic by-products that may also be toxic [321]. Products of partial ozonization of MMH included methanol, formaldehyde, formic acid, and formaldehyde methylhydrazone. Products of partial ozonization of UDMH included acetone, formaldehyde methylhydrazone, formaldehyde dimethylhydrazone, NDMA, dimethylformamide, and tetramethyltetrazene. Aquatic bioassays with fish and *Daphnia* indicated that the toxicity of the propellant rinse waters was somewhat reduced as the result of ozonization. Again, it must be emphasized that ozonation alone is not completely effective in decontaminating MMH-contaminated wastewater. Mechanisms of various photolytic reactions of hydrazines and nitrosamines are summarized in Section 4.3.

The NASA WSTF acquired an ozone generator capable of producing 2.75% ozone in oxygen and installed it in a pilot-scale reactor [556–558]. It was important to feed the ozone generator with dry oxygen and maintain its temperature below 287 K to optimize the ozone yield. The UV ozonator reactor was a rectangular chamber with six spray nozzles capable of flowing 3.8 L/min and atomizing the liquid into a fine spray. The residence time of the droplets during each passage was ~14 s. Twenty-three low-pressure UV lamps rated at an average output of 6.6 W of UV light were mounted through the sides of the chamber. The power consumption of the UV lamps was 152 W. The liquid containing 300–700 ppm MMH to be treated was circulated by pumps and flowed back into a sump. The liquid (132 L/batch) was recirculated until the desired destruction level (non-detectable level of NDMA) was achieved. Experiments with hydrazine lasted 78 h, MMH 180 h, and UDMH 334 h. It was detected that one of the slowest, rate-determining steps is the oxidation of methanol to formaldehyde. Ozone dissolves in cold water better than in hot water. Dissolved ozone continues to react during extended storage of solutions in the sump in the dark and the MMH-derived chlorine-oxidizable contaminant level continued to drop slowly during inactive off-time, while the treated waste was stored in a pond.

The NASA WSTF then fabricated and tested a full-scale 85.2-m<sup>3</sup> (2,250-gal) hydrazine wastewater treatment system [559]. The system was based on an IITRI design featuring the use of ozone and UV to destroy the hydrazines and NDMA. A series of 21 tests evaluated the performance of the system using synthetic mixtures of hy-

drazine, MMH, and UDMH at concentration levels of 100 and 3900 ppm. In addition, one of these tests was performed on actual wastewater obtained from a Vandenberg Air Force Base launch site sump. The tests demonstrated that the UV ozonization system would satisfactorily reduce the hydrazine concentration to less than 5 ppb and the NDMA concentration to less than 100 ppt.

### 7.9.2 MMH Wastewater Decontamination by Reaction with Hypochlorite

The reaction of MMH with sodium hypochlorite does not go to completion and a large number of oxidation products form. Nearly 30% of the original nitrogen remains in solution in the form of different nitrogen compounds. During the treatment, the solution gradually turned yellow as more hypochlorite was added. The color persisted if the solution was allowed to stand after the gas evolution had ceased [526]. Addition of carbon dioxide to MMH solutions prior to neutralization with liquid bleach increased the number of organic products seen in the reaction mixture.

### 7.9.3 MMH Wastewater Decontamination by Reduction Treatment

Dilute aqueous solutions of hydrazine, MMH, or UDMH can be decomposed by catalytic reduction with nickel/aluminum (Ni-Al) alloy under basic conditions [560, 561]. The reaction is based upon dissolution of Al from the Ni-Al alloy in aqueous media to form aluminum ion and hydrogen gas. The resultant finely divided nickel catalyzes reduction of the hydrazine, nitrosoamine, and/or nitroamine by the hydrogen produced. Greater than 99% of propellants contained in dilute hydrazine or MMH aqueous solutions were decomposed when reacted with Ni-Al alloy in 0.5 M sodium hydroxide. The major reaction product of MMH was methylamine. Control experiments with plain Al powder rather than Ni-Al alloy showed no effect on hydrazine, MMH, or UDMH. Spill pillows containing Ni-Al alloy and solid sodium hydroxide were also tested and found to be effective in the absorption and decomposition of MMH in aqueous solutions. These results showed that reductive decomposition of hydrazine, MMH, or UDMH is a promising method for propellant hydrazine(s) waste water treatment and spill control.

### 7.9.4 MMH Wastewater Decontamination by Bioremediation

The disposal of wastewater containing hypergolic propellants (including MMH rinse waters) by keeping them in an open holding pond with bioregeneration through water hyacinths has been tested in Florida [525, 562]. The products of the scrubbing reaction of MMH and NaOCl are  $\text{CH}_3\text{OH}$ ,  $\text{CH}_3\text{Cl}$ ,  $\text{CH}_2\text{Cl}_2$ ,  $\text{CHCl}_3$ , and  $\text{CH}_4$ . The waste MMH scrubber liquor consisted of aqueous solutions containing small amounts of  $\text{CH}_3\text{Cl}$ ,  $\text{CH}_2\text{Cl}_2$ , and  $\text{CHCl}_3$  as well as large amounts of  $\text{CH}_3\text{OH}$ . This waste was scheduled to be disposed of in stabilization ponds along with nitrate and nitrite salt solutions obtained as waste liquors from the  $\text{N}_2\text{O}_4$  scrubbers.

Effluent from an MMH scrubber can be neutralized and kept in a holding pond for complete oxidation and interaction with aquatic plants [563]. Active contributions by sunlight-induced neutralization–oxidation reactions may accelerate the biological process.

## 7.10 Personnel Protection Equipment for MMH

Protective clothing to be worn by personnel in the vicinity of a pressurized MMH system depends on the type of operation to be performed [564]. A group of 28 glove materials, 9 suit materials, and 3 other materials were tested for permeability to MMH, hydrazine, or NTO following exposure to these propellants for 90 min. [565, 566]. Breakthrough times were calculated for predefined “breakthrough” concentrations of 16 ppb MMH and saturation concentrations of 1.6 ppm MMH. These breakthrough times were tabulated for several samples of each material used in the tests. Breakthrough times were determined and correlated with static permeation rates. Of the 28 glove materials, 9 had breakthrough times for hydrazine of less than 90 min. (2 of these shorter than 10 min.), 1 was marginal, 3 had barely detectable permeation, and 15 resisted permeation for at least 90 min.. The comparable times for MMH were much shorter, namely 19, 5, 1, 1, and 7 min. This indicated that it is more difficult to find good gloves for MMH protection than for hydrazine protection.

Several decontamination procedures for personal protective suit materials in use at NASA WSTF, including Chloropel (a chlorinated polyethylene) were tested after the material was subjected to NTO or MMH [567]. Each exposure sequence was followed by a simple room temperature water wash decontamination sequence. Two versions of heated decontamination sequences were used: **(1)** a simple purged heated sequence, and **(2)** a heated evacuation sequence. After the second water decontamination sequence these two versions of heated decontamination sequences were used to further reduce the concentration of residual fuel trapped in the material.

### 7.10.1 Gas Masks for Protection Against MMH Vapors

The MSA rocket propellant gas mask canister BMN-SSW has an indicator that changes color when the capacity of the gas mask is exhausted. Its absorbing capacity for MMH has been determined [568].

### 7.10.2 Full-Body Suits for Protection Against MMH

In hypergolic propellant spill tests at NASA WSTF, it was determined that the exterior of the protective equipment may be exposed to vapor concentrations as high as 800 ppm MMH. These results were then used for permeation testing of different protective clothing materials [569, 570].

The self-contained atmospheric protection ensemble (SCAPE) suits used at NASA launch sites are made from a chlorobutyl-coated Nomex fabric. The fabric and its coating is subjected to wear and tear and its integrity needs to be monitored daily [571].

Splash evaporation tests of propellants spilled on space suit materials at three different initial sample temperatures showed that most propellant spills freeze almost immediately in vacuum [572, 573]. Hydrazine supercooled to 355 K and then froze to ice, which was near the triple-point temperature. The force needed to scrape frozen hydrazine from the material sample by scraping and the time needed to sublime frozen hydrazine under one solar flux (simulated with a heat lamp) was measured. MMH did not freeze but evaporated before much ice could form. MMH was the only propellant that visually damaged the suit material. Aluminized Mylar layers were found to be dissolved in the area where the propellant had impinged on the fabric. Supercooled MMH dissolved the aluminized Mylar layers of the suit ensemble, and both hydrazine and MMH caused cracking in the polycarbonate helmet visor, but not in the helmet material alone.

Permeation resistance was determined by measuring the breakthrough time and time-averaged vapor transmission rate of MMH through the fabric of two types of personal protective equipment (PPE) suits [574]. The two types of PPE evaluated were the totally encapsulating ILC Dover Chemtursion, Model 1212 chemical protective suit and the FabOhio polyvinyl chloride (PVC) splash garment. Two exposure scenarios were simulated: **(1)** a saturated vapor exposure for 2 h, and **(2)** a brief MMH “splash” followed by a 2-h saturated vapor exposure. Time-averaged MMH concentrations inside the totally encapsulating suit were calculated by summation of the area-weighted contributions made by each suit component. Results showed that the totally encapsulating suit provides adequate protection at the new 10-ppb Threshold Limit Value Time-Weighted Average (TLV-TWA). The permeation resistance of the PVC splash garment to MMH was poorer than any of the totally encapsulating suit materials tested. Breakthrough occurred soon after initial vapor or “splash” exposure

Calculations showed that the maximum allowable permeation rates of hydrazine fuels through chlorinated polyethylene were of the order of  $0.05$  to  $0.08 \text{ ng cm}^{-2} \text{ min}^{-1}$  for encapsulating suits with low breathing air flow rates (of the order of 5 scfm or 140 L/min.) [575]. Above these permeation rates, the 10 parts-per-billion (ppb) TLV-TWA could be exceeded.

## 8 Materials of Construction for MMH

Quite often data for a particular material of construction may be available for one of the other three propellant hydrazines, but not for the hydrazine of interest. To a limited extent, it is possible to extrapolate metals compatibility data from one hydrazine to another. For metallic materials, the extrapolation is easier than for non-metals. Metals found to be compatible with hydrazine are most likely to be compatible with MMH and

UDMH too. Similarly, metals found to be compatible with MMH are most likely to also be compatible with UDMH. Polymeric organic materials are more likely to swell in UDMH than in MMH or hydrazine.

Materials compatibility data available from the literature often do not normally distinguish between static and dynamic compatibility, yet flowing propellants can be much more corrosive than what is observed in a static immersion test.

## 8.1 Materials Compatibility Test Methods

Experimental methods for determining the compatibility of hydrazine(s) fuels with materials of construction were already described in *Encyclopedia of Liquid Fuels*, chapter “Hydrazine.” Methods that have been successfully used for anhydrous hydrazine  $N_2H_4$  can equally well be used for MMH and UDMH and their mixtures.

### 8.1.1 Short-Term Exposure Tests

Before one endeavors to start long-term materials compatibility tests, a quick screening test is useful to eliminate materials that are obviously incompatible. Such open-air, visual observation tests in a Petri dish will also need to be performed on materials that are not necessarily wetted with hydrazine by design, but may be exposed to hydrazine in the case of an accidental propellant spill during fueling or a leak. A procedure for casual exposure of materials to hypergolic fluids has been developed [576]. A “casual” exposure is assumed to last less than 240 min. Fabric and splash shield and goggle materials intended to be used for PPE need to be subjected to more rigorous tests.

### 8.1.2 Medium-Term Exposure Tests

Before any material of construction in contact with MMH is allowed to fly on NASA missions, the reactivity of MMH with such materials of construction must be tested in accordance with NASA-STD-6001B Test 15 [577]. This test was previously published as part of NASA Handbook (NHB) 8060.1. In this apparatus, two identical test chambers made of Pyrex glass partially filled with MMH are connected to pressure transducers, but only one chamber contains the material sample under test immersed in MMH. The apparatus is immersed in a constant temperature bath at 344 K (71 °C = 160 °F) and the test is continued for 48 h. The pressure rise is not allowed to exceed the pressure rise measured when the same test is done with a reference material, CRES-304 for metals and Teflon for non-metals. In the case of the hydrazine fuels, the gas evolution rate is  $<7.0 \times 10^{-3}$  standard  $cm^3\ cm^{-2}\ h^{-1}$ . The post-test specimen is weighed and examined for changes in appearance, dimensions, and tensile strength. The off-loaded MMH liquid is analyzed for leached contaminants. Similar tests are done in the same apparatus for compatibility of materials with UDMH, anhydrous hydrazine, or dinitrogen tetroxide.

## 8.2 MMH Compatibility with Metals

Many summaries and survey papers on materials compatibility have been published, of which the following few may serve as starting points for further study. Most of these publications deal with more than one propellant, so the MMH data needs to be sorted out and separated from the rest of the data. A good summary of materials compatibility data for MMH is in the NASA WSTF MMH Manual [90].

A survey on MMH material compatibility (now obsolete) tried to assemble literature data on materials compatibility, but yielded only a few hard fact data [578]. The 6-year interim status report of the materials compatibility tests at JPL at 316 K (43°C) included data on CRES-303, CRES-304L, Ti-6Al-4V, and Al-6061-T6, which were considered acceptable and continued in tests with MMH, but samples of CRES-347 in MMH showed slight corrosion and it was rated as not acceptable for 10-year missions [239]. However, DOT allowed MMH to be shipped in CRES-347 containers. Initially, more than 700 test ampoules (including some with MMH or NTO) were placed in long-term storage testing at 316 K (110°F). Intermediate results after up to 5 years in storage at 316 K (110°F), based on the opening of 108 ampoules including 4 ampoules containing MMH were reported in [239]. At that time (1976), 578 specimen capsules remained in active test, and some were scheduled to remain in test for a full 10 years.

Additional tests with MMH at JPL included the materials Al-5052, Al-5083, Al-5086, Al-5154, Al-5254, Al-5454, Al-5652, Al-6061, and CRES-316, CRES-316L, and CRES-430 as single coupons and also in the welded form [579]. Storage tests were conducted using specification-grade MMH and a special grade (doped with water and carbon dioxide) for a period of 123 days at a temperature of 344.2 K (71.1°C = 160°F). Based upon the experimental test results, it was concluded that **(1)** aluminum alloy types 5052, 5086, 6061, and CRES types 316, 316L, 321, and 430 are compatible with both grades of MMH, and **(2)** that these materials and similar generic types would be suitable materials for use as shipping and storage containers for MMH propellant.

The 10-year compatibility results milestone report contained the results of the opening and examination of 36 ampoules containing hydrazine and 8 with MMH [228, 229]. After 10 years, 164 specimens plus 28 hydrazine controls remained in storage.

It is unfortunate that many materials compatibility studies did not specify the grade of MMH used, which may have contained various amounts of impurities that would have affected the metal compatibility. Some materials compatibility tests may have contained a trace of CFC-113 (Freon® TF), which was used as a cleaning fluid and not completely removed from the ampoules before inserting the samples. If hydrazine, MMH, or UDMH becomes accidentally contaminated with halocarbons, the corrosion of braze joints and the resulting rate of gas evolution is extremely bad [580, 581].

The selection of materials of construction has become very difficult for long-term space missions because frequently insufficient real-time, long-term storage data are available. The time available until the decision date/launch date is often too short to conduct a real-time evaluation. Many missions now exceed 15 years of design life. The

need for a test that allows metals compatibility testing to be accelerated was the driving force behind the development of an electrochemical test method [582]. Although this method was mostly used for anhydrous hydrazine, 2.1–3.1%  $\text{H}_2\text{O}$  as well as 10 and 30 ppm  $\text{Cl}^-$  were tested in MMH to demonstrate the usefulness of this accelerated compatibility test method for other propellants. Small amounts of  $\text{Cl}^-$  made  $\text{N}_2\text{H}_4$  or MMH incompatible with Al-6061-T6.

Metallic materials found to be acceptable for anhydrous hydrazine service are generally acceptable for MMH or UDMH service as well because hydrazine is a stronger electrolyte and more corrosive. For non-metallic polymeric materials, the organic hydrazines may cause more swelling and permeation than anhydrous hydrazine. In MMH, a very thin oxide coating was noted on two Al-6061-T6 specimens after 10-year storage at 316 K [228]. Although up to 100 ppm Al was found to be dissolved in the propellant, no catalytic effect was noted. Both CRES-304L and -347 exhibited minor corrosion and caused MMH discoloration. Analysis of off-loaded MMH showed 100 ppm Fe. Surprisingly, even Ti-6Al-4V showed some corrosion in MMH. Corrosion products were deposited in the vapor-exposed area and at the liquid–vapor interface. A small quantity of sediment was detected in a capsule that also contained chloride contamination. All three metals were rated acceptable for MMH service, but only a small number of off-loaded propellant samples were analyzed.

If MMH becomes accidentally contaminated with halocarbons (chlorofluorocarbon cleaning fluids or lubricants), the corrosion of braze joints is extremely bad [581, 583]. Sometimes halogenated solvents were used to clean only the pressurant gas system, which ordinarily would never be exposed to hydrazine(s), but pressurant gas carried residual solvent vapors into the propellant tank, where it reacted with MMH. In reproducing the problem in the laboratory, MMH was doped with 0.25 to 2.5% Freon-TF, and 96Sn/4Ag solder, Ti-6Al-4V, iridized aluminum 6061-T6, and stainless steel samples were immersed in the adulterated propellant for 63 days, becoming corroded. Corrosion in Freon-contaminated hydrazine or MMH was not caused by chloride. However, metal corrosion occurred when specimens were exposed to hydrazine and MMH that had been doped with hydrogen fluoride. A possible mechanism for formation of hydrogen fluoride includes dechlorination of Freon to form chlorotrifluoroethylene ( $\text{CFCl}=\text{CF}_2$ ), which then reacts with hydrazines to liberate fluoride.

Because a complete compilation of all materials compatibility data with hydrazine fuels would easily fill another book equal in volume to this, a compromise format had to be sought in presenting materials compatibility data here. Therefore, Table 40 serves mostly as a guideline without providing too much detail for locating additional information on materials compatibility.

Many of the reports referenced here deal with more than one propellant in addition to MMH. Sometimes the same report contains valuable additional information on dinitrogen tetroxide (NTO) or other rocket propellants, which were already discussed in *Encyclopedia of Oxidizers*.

**Table 40:** Literature references to compatibility of metals with methylhydrazine.

| Material                | Ullage pressure rise | Weight change of test coupons | Analysis of residual MMH | Tankage and tensile tests | Stress corrosion     |
|-------------------------|----------------------|-------------------------------|--------------------------|---------------------------|----------------------|

Even after published data are located, there are often serious questions and some doubt about the reliability of these data and their applicability to the current materials selection task at hand. None of the publishers accepts any responsibility for the accuracy of these data. The conditions under which the compatibility was determined vary widely from laboratory to laboratory and there are only a few standardized test procedures.

### 8.3 MMH Compatibility with Aluminum Alloys

The aluminum alloys Al-1100-0, Al-2014-T6, and Al-2219-T87 were rated compatible with MMH for 300 h at 135 °C, with no corrosion or MMH decomposition [590, 591]. In looking for materials for advanced spacecraft valves, several hundred literature references on 21 different propellants that were in use as of 1967 or anticipated to be used within the next 10 years, including MMH, were assembled, but the report on pages 1-20 through 1-22 lists only material and temperature for compatibility, not duration of im-

mersion [592]. The report indicated that Al-3003, Al-5052, Al-5154, and Al-6061 alloys were compatible with MMH at 373 K (100 °C) or below for short-term use (2 weeks) [593].

Other propellant material compatibility tests at high temperatures showed an exothermic reaction of Al-2014-T6 and Al-6061-T6 alloys with MMH at temperatures in the 658–663 K (385–390 °C) range, which was lower than what was observed with CRES alloys [247]. No relationship with compatibility at lower temperatures could be inferred.

Heating MMH to 373 K (100 °C) for 7 days in contact with aluminum alloys Al-1100, Al-2014, Al-6061, corrosion-resistant steels types 321, 347, 17-7, and Inconel X-750 showed no increase in the decomposition of propellant and no noticeable corrosion of the metal surfaces [230].

In MMH, a very thin oxide coating was noted on two Al-6061-T6 specimens after 10 years at 316 K [228]. Although up to 100 ppm Al was found to be dissolved in the propellant, no catalytic effect was noted. Surprisingly, even Ti-6Al-4V showed some corrosion in MMH. Corrosion products were deposited in the vapor-exposed area and at the liquid–vapor interface.

#### **8.4 MMH Compatibility with CRES Alloys**

There was no significant corrosion or propellant decomposition with CRES-303 in contact with MMH for 1368 days at 316 K (43 °C) or with CRES-304L for 130 days at 316 K (43 °C) [239]. Corrosion was limited to faint tarnishing of the specimens. Approximately ten other test specimens (CRES-303, CRES-304L, CRES-316, CRES-347) were still undergoing testing, and after 6 years of exposure to MMH at 316 K (43 °C) no serious corrosion or propellant decomposition effects were noticeable.

The inlets to propellant valves are usually protected by filters to retain particles that might get lodged on the valve seat and cause the valve to leak when it is commanded shut. The screen material on the filters has to be compatible with the propellant, which in the case of hydrazines is not as difficult a task as with oxidizers. The corrosion product (carbazate, carbonate) film growing on the thin metal wires might cause a narrowing of the passages and increase the pressure drop or embrittle the wires. Similar wire mesh is used in surface tension propellant management devices in propellant tanks for zero-g operation. The long-term effects of propellant immersion on fine micronic stainless steel wire cloth were studied for hydrazine, MMH, and UDMH, and six other propellants [594, 595]. Immersion times reported in the literature ranged from 3 months to 7 years.

The stability and materials compatibility of MMH are greatly affected by the presence of impurities. Among the factors affecting the compatibility of MMH with stainless steel are the chemical composition of the oxide layer on the metal and the surface roughness. A number of techniques for modifying the Cr/Fe ratio at the 304L stainless steel surfaces were investigated [353]. It was concluded that thermal oxidation

gives the highest ratio (measured using X-ray Photoelectron Spectroscopy) followed by electropolishing, chemical treatments, and mechanical treatments.

## 8.5 Stress Corrosion Cracking in MMH

Most stress corrosion tests with various stressed (loaded) metal specimens are conducted in salt water environments. For many missiles or launch installations on coast lines, this may be an external rather than internal exposure condition. Magnesium chloride solutions are often used to produce worst case conditions simulating sea water. MMH is not a strong electrolyte, but contaminants, in particular chloride, in MMH can lead to crack growth and rupture of stressed metal, typically in pressurized tank walls.

Although AISI 4130 is generally not recommended for anhydrous hydrazine service because it rusts too easily, it is compatible with MMH and UDMH, based on static compatibility test results. With 4130 no crack extension occurred in UDMH up to at least 2000 h, whereas MMH caused growth after 500 h and hydrazine, after about 60 h. Stress corrosion susceptibility was evaluated for several alloys in hydrazine-type fuels [584]. The evaluation was on the basis of crack growth in wedge opening loaded fracture specimens. The alloys tested were classified in order of decreasing susceptibility as follows: CRES-4130, CRES-410, Inconel 718, Ti-6Al-4V, Al-6061-T6. The aluminum alloys showed no susceptibility. The order of decreasing stress corrosion cracking promotion for the fuels was hydrazine > MMH > UDMH. Crack growth susceptibility is related to contamination levels of water and carbon dioxide.

An investigation of the stress corrosion susceptibility of Ti-6Al-4V alloy in various fluids was initiated because of failures of this alloy in both dinitrogen tetroxide and absolute methanol. The study indicated that Ti-6Al-4V alloy is susceptible to stress corrosion cracking in absolute methanol in the annealed, solution-treated, and aged conditions. The threshold value for annealed material appeared to be near 50% of the yield strength or approximately 70000 psi, whereas the value of solution treated and aged material was somewhat less. Long-term exposure tests (2 years) indicated that the Ti-6Al-4V alloy is not susceptible to stress corrosion cracking in MMH, Aerozine-50, distilled water, absolute ethanol, Freon PCA, Freon MF, hydraulic oil (MIL-H-5606), acetone, absolute isopropanol, RP-1 fuel or trichloroethylene [585]. The titanium alloy Ti-15V-3Al-3Cr-3Sn (which allows the shear-spin forming of propellant tank hemispheres much more readily than Ti-6Al-4V) is not susceptible to stress corrosion in MMH for 1000 h at 322 K (120 °F). Sustained-load tests were performed at 322 K (39 °C) up to 1000 h with thin-gauge tensile specimens containing semi-elliptical surface flaws and stressed to 80% of the critical plane-strain stress-intensity factor.

## 8.6 MMH Compatibility with Non-Metallic Materials

Just as hydrazine and alkylhydrazines may attack metals, hydrazines may also alter chemical bonds and mechanical properties of organic polymers. Non-metallic materials are needed as gaskets, seals, containment bladders, diaphragms, and lubricants. In addition, it has been attempted to replace metals with lighter-weight engineering thermoplastics in support structures and tank walls where they would be in constant contact with the hydrazines. It has been very difficult to find totally compatible materials for each of these applications. Polymers found to be compatible with UDMH are most likely also compatible with MMH and hydrazine; similarly, polymers found to be compatible with MMH are most likely also compatible with hydrazine, but polymers known to be compatible with hydrazine may dissolve or swell in either MMH or UDMH.

Kalrez (“the material born to fly”) is often used for MMH gaskets in bipropellant systems, but is not suitable for hydrazine in monopropellant systems [242]. Kynar 460 may cause problems in MMH in contact with steel [596]. The exothermicity of MMH and Kynar was tested by DSC [597]. Teflon is the most inert polymer for gaskets and seals, yet at very high temperatures it can react with hydrazine or MMH and release fluoride ions [598].

Thermoplastic liquid crystal polymers including Vectra A 625 and Vectra C 950 were evaluated as components for MMH propellant turbopumps [599, 600]. The weight loss after only 7-day immersion in MMH was excessive, 11.6 to 22%, and these materials have no use in an MMH environment.

Composite overwrapped tanks with a thin metal shell allowed considerable mass savings in spacecraft design. If propellant is accidentally spilled on the outside or it leaks through a pinhole in the shell, the integrity of the composite overwrap may be jeopardized and the tank may burst [601].

An O-ring material used in storable propellant components on many NASA spacecraft designs was discontinued by the manufacturer and NASA’s stockpiles were expected to be depleted soon. NASA NESC initiated a materials compatibility characterization effort to evaluate multiple replacement material options. Material properties of multiple replacement candidates were tested, looking at weight change, swelling, hardness, compression set and tensile strength in representative environments to help identify suitable replacements [602]. See also [603].

### 8.6.1 Positive Expulsion Bladders and Diaphragms for MMH

Standard Teflon/aluminum laminate bladders employed as MMH zero-g propellant management devices on Mariner Mars 71 space probe failed because of cracks and tears near an aluminum seal ring that formed the mouth of the bladder [604]. These failures occurred during flight-acceptance tests with inert solvents (Freon TF and isopropanol) used as simulant fluids. It was found that one of the laminate polymers, FEP

120, was particularly solvent-sensitive and it was then eliminated from future laminates for expulsion bladders.

Seamless Teflon-positive expulsion bladders were used for MMH and Aerozine-50 propellants on Apollo Command Module, Service Module, Lunar Descent Module, and even on the S-IVB upper stage RCS [605]. A similar bladder was used for MMH on the unmanned Lunar Orbiter velocity control system.

Composite Teflon–aluminum foil bladders were evaluated for the Surveyor lunar lander vernier propulsion system in an effort to reduce helium permeation and propellant (MON-10 or MMH/H<sub>2</sub>O) saturation with pressurant gas [606, 607]. If the propellants were partially or fully saturated with helium, the large quantities of gas coming out of solution and the resulting two-phase flow decreased the dynamic response of the vernier engines. Propellant permeation into the ullage space was only a minor problem.

Bladders tested were initially made of multiple sprayed layers of tetrafluoroethylene (TFE) and fluoroethylene propylene (FEP). TFE was manufactured similar to a sintered powder metallurgical part by compressing the powder. FEP was similar in character to a true thermoplastic material. The major problem was bladder tearing during three-axis vibration, in particular at the lower temperature range [608, 609].

The ERIS projectile used two each of the NTO and MMH tanks in a cruciform structure in two opposing quadrants [610]. Both inner and outer rolling diaphragms were made of soft Al-1100-0. A thickness of 0.5 mm (0.020 in) was optimal with regard to rigidity under high-g loads and stiffness and resistance to feed pressure  $\Delta p$ . During expulsion, pressure acting on the piston surface peeled both the inner and the outer diaphragm away from their respective walls. The piston moved down the tank axis until it bottomed out. The Al-2219 composite-overwrapped pressure vessel (COPV) tanks were rated for an operating pressure of 2550 psia and 10 g axial, 4 g lateral acceleration. These tanks were instrumental in several successful flight tests. Other tanks were stored for 1 year and the contents fired through a set of thrusters in ground tests.

### 8.6.2 Lubricants for MMH Service

A perfluoro polyether grease made by DuPont, Krytox 240, appears to be compatible with hydrazine and MMH based on gas evolution measurements and corrosion of the metals [592]. Krytox greases contain a polymer of tetrafluoroethylene and perfluoroalkylpolyethers of the general formula  $F[CF(CF_3)CF_2O]_nCF_2CF_3$ . Krytox 240AC was widely used for servicing the Space Shuttle OMS/RCS bipropellant systems and did not interfere with the combustion process in a bipropellant engine.

### 8.6.3 Tubing for MMH Samplers

The selection of materials for the propellant vapor manifold for remote sampling of MMH vapors in rocket launch sites or during animal exposure tests required a special study. There was not so much concern about MMH inadvertently destroying

the tubing as concern about samples hanging up in the tubing on their way from the sampling location to a central analyzer. It was shown that with MMH, substantial MMH losses were incurred in metal tubing, and best results were obtained with tubing made from perfluorinated polymers [611]. The plastics tested for MMH and UDMH sampling included polyethylene-lined ethyl vinyl acetate, high-density polyethylene (HDPE), polypropylene, Teflon TFE (polytetrafluoroethylene), Teflon FEP (polytetrafluoroethylene–polyhexafluoropropylene), and Teflon PFA (polytetrafluoroethylene–perfluoropropyl vinyl ether) [612]. All tubing performed in an approximately equal manner with regard to sample retention, response time, and ease of cleanout with methanol. Although the polyethylene-lined ethyl vinyl acetate tubing appeared most suitable for MMH, Teflon FEP, and HDPE performed best for UDMH sampling.

Unrecognized vapor loss by permeation and oxidation in incompatible plastic tubing has thrown severe doubt on the validity of animal inhalation toxicity test results with hydrazine(s) vapors conducted in the 1980s. The animals were inadvertently exposed to concentrations of toxic vapors that were orders of magnitude higher than what the analysis instrument at the end of a long sampling line indicated.

## 8.7 Cleaning Agents for MMH Systems

The reactivities of several selected halogenated precision cleaning solvents with MMH have been determined by analysis of the rates of formation of halide ion decomposition products [613]. The solvents tested were Asahiklin AK 225, Asahiklin AK 225 AES, HFE 7100, HFE 7100 DE, Vertrel XF, Vertrel MCA, Vertrel MCA, Plus, 1,1,2-trichloro-1,2,2-trifluoroethane (CFC-113), and trans-1,2-dichloroethylene (DCE). All of the solvents except DCE exhibited significant reactivity with MMH, particularly HFE 7100 DE and CFC-113.

# 9 Propellant System Components for MMH

## 9.1 Propellant Flight Tanks for MMH

The second edition of the hydrazine book contained two tables with flight propellant tanks for hydrazine and MMH [22]. It has not been possible to keep those tables up-to-date and therefore they have been eliminated from the current book. New tank designs become available every year and it is difficult to keep this table up to date.

Many tank suppliers have changed names and/or ownership since they first started making propellant tanks. The name shown in earlier tables may not be the name under which the company currently operates. Many MMH tanks can also be used for NTO oxidizers with only minor modifications and changes of the part

number. Satellite designers prefer both tanks to be from the same supplier to facilitate integration and center of mass control. Although a table for hydrazine tanks would include both diaphragm (bladder) and surface tension PMD tanks, a table for MMH would show exclusively surface tension PMD or PMD-free tanks. This is because bipropellant satellites and bipropellant fuel tanks tend to be bigger than hydrazine monopropellant tanks and diaphragms and bladders can only be built up to a certain size. Only very few MMH diaphragm or bladder tanks were ever built.

Surface tension and contact angles of MMH must be known for the design of surface tension tanks for use in a zero-g environment in space. Surface tension tanks have fine-mesh screens in the forms of chimneys, vanes, and galleries to collect and hold propellants in position near the tank outlets even in a zero-g environment, such that only liquid and no pressurant gas can enter the engines [614–616].

## 9.2 Propellant In-Space Gauging

The difficulties in estimating remaining propellant in a propellant tank in a satellite in space and predicting the remaining useful life of the satellite apply to all liquid propellants, not only to MMH. A brief discussion of propellant gauging methods was already provided in *Encyclopedia of Liquid Fuels*, chapter “Hydrazine.”

Three Insat satellites using NTO/MMH bipropellant for both apogee firing and on-orbit station keeping and attitude control used careful propellant consumption book keeping in combination with telemetered residual tank pressure data to predict remaining propellants at the end of the mission [617, 618]. The system operated with regulated helium pressure during apogee firings and orbit insertion, then isolated the pressurant tank from the propellant tanks and continued to operate in a blowdown mode. Analytical models were developed to predict the bipropellant propulsion subsystem performance. The NTO/MMH unified bipropellant propulsion system flown on the OLYMPUS and ITALSAT satellites was very similar to the INSAT in that it also operated with regulated helium pressure during apogee firings and orbit insertion, then isolated the pressurant tank from the propellant tanks and continued to operate in a blowdown mode [619]. Propellant gauging depended on record keeping and telemetry of blowdown mode feed pressure decrease. After all other means of propellant gauging are exhausted, most spacecraft designers ruefully come back to the good old PVT methods, and computer simulations of flight systems help to understand telemetry data or data from drop tower zero-g simulation tests [620].

## 9.3 In-Space Propellant Shifts

Thermal pumping between connected tanks in satellites with multiple tanks has already been identified as the cause of unwanted center-of-gravity shifts. In addition,

even in satellites with individual, single tanks with surface tension PMDs, temperature differentials can cause unexpected migration of propellant from one screen compartment to another by evaporation and condensation [621]. This would apply to all propellants, not only to MMH. It is important that the compartment next to the outlet remains filled as long as possible or the propellant delivered to the thrusters will begin to ingest pressurant gas bubbles.

#### 9.4 Flow Control Valves for MMH

There are many, many enable valves, check valves, latching valves, and flow control valves available for MMH service both on the ground and in flight vehicles, and a supplier survey would have to be updated every few months.

Extrusion of a polytetrafluoroethylene (PTFE) pilot seal located in the Space Shuttle Orbiter Primary Reaction Control Subsystem (PRCS) thruster fuel valve has been implicated in 68 ground and on-orbit fuel valve failures. A rash of six extrusion-related in-flight anomalies over a six-mission span from December 2001 to October 2002 led to the formation of a multi-disciplinary team to solve the problem [622, 623]. Propellant exposure tests showed that some extrusion is produced by thermal cycling; however, a review of thruster service histories did not reveal a strong link between thermal cycling and extrusion. Failure analysis of failed hardware revealed the presence of fuel–oxidizer reaction product inside the fuel valve pilot seal cavity, and DSC showed that the residue (MMHN) was intimately associated with the pilot seal material problem. Residue of similar composition could be produced by adjacent oxidizer valve leakage even in the absence of thruster firing. See also [624].

### 10 Safety Properties of MMH

Handling safety properties include, besides toxicity (which is discussed in detail at the end of this chapter), predominantly flammability and detonability. This section deals with safety properties for MMH and MMH mixtures. This chapter is restricted to the conditions conducive to (inadvertent) vapor decomposition or combustion, whereas more academic studies of the decomposition or combustion mechanism and kinetics are discussed in Section 4.1. For detonability, only limits of detonability and required modes of initiation are discussed here.

Useful summaries of the hazard properties of MMH and other rocket propellants have been published by several organizations, including the Air Force Space Propulsion Hazards Manual *Space Propulsion Hazards Manual* [516–518], a three-volume series useful for the design of ground-service equipment and the planning of fueling operations. Another very useful three-volume series is the *Hazards of Chemical Rockets and Propellants* handbook published by the former CPIA. Volume 1 deals with safety,

health, and the environment [625]. Volume 2 is for solid propellants (not yet discussed here), and Volume 3 is for liquid propellants [626]. NASA WSTF has put together three very practical handbooks, one on *Ignition and Thermal Hazards of Selected Aerospace Fluids* (including hydrazine, MMH, UDMH, and Ae-50) [627], one on *Fire, Explosion, Compatibility, and Safety Hazards of Monomethylhydrazine* [90], and a similar handbook on *Fire, Explosion, Compatibility, and Safety Hazards of Hydrazine* [243]. These handbooks were originally published in loose-leaf format in a ring binder and could be updated periodically. Two of those were later also published by the American Institute of Aeronautics and Astronautics (AIAA) under the aerospace specification series [90, 628]. These handbooks and other survey papers such as the comparison study of explosion hazards of hydrazine and MMH in aerospace launch vehicle environments [241] cite numerous WSTF test reports as references, but most of these cited reports have unfortunately never been deposited with NTIS and are not available to the general public. When MMH first became available, hydrazine(s) manufacturers published summaries of the safety properties of MMH, but these are now out-of-date [1].

Uncertainties with regard to vapor pressure can make it difficult to accurately predict hazards from propellant vapors, and how long it would take to vent propellant vapor residues remaining in a test area after a leak or an accident [93].

### 10.1 Flash Point of MMH in Air

The “ignitability” or, scientifically more accurately, the flash point, is determined by heating the liquid in an open cup and moving a pilot flame back and forth over the surface until the pool in the pan catches on fire. This test using brass cups is extensively used for characterization of petroleum products. The Cleveland open-cup method is described in ASTM Method D92-85 and the Tag closed-cup method is described in ASTM Method D56-82. Another Tag open-cup flash point test is described in ASTM Method D1310-86. Because hot MMH reacts with brass, a glass insert must be used for MMH tests. Occasional puffs of ignition are observed below the flash-point temperature when the pilot flame is moved across the surface, but sustained combustion may or may not occur. The temperature above which sustained combustion occurs is called the “fire point.”

The flash point of hydrazine itself is significantly higher than that of its methyl derivatives, MMH (294 K = 70 °F) or UDMH (274.2 K = 34 °F; all three data based on the Cleveland open cup method). Both MMH and UDMH are classified as flammable liquids.

The Lonza-Arch web site lists an MMH Cleveland Open-Cup flash point of 294.2 K (21.1 °C = 70.0 °F). Differing flash points of MMH were reported earlier by Olin: a Tag Open-Cup flash point of MMH in 1962 (17 °C = 290 K), and a Cleveland Open-Cup flash point in 1986 (21.1 °C = 294.2 K). Either one of the two differs from later testing

performed by NASA in a Tag open-cup tester [629]. The NASA tests gave a Tag open-cup flash point of  $7^{\circ}\text{C} = 280\text{ K}$  (corrected for sea level conditions), 10 K lower than the Olin data point. At the high altitude above sea level of White Sands with an atmospheric pressure of only 0.85 bar (12.4 psia), the measured flash point of 99.5% MMH was  $-2^{\circ}\text{C} = 271\text{ K}$ . The pressure correction to report data for sea level pressure by adding 9 K was derived from earlier tests with other flammable fluids. The effect of water dilution on the Tag open cup flash point of MMH is shown in Figure 33.

**Figure 33:** Flash and fire points of methylhydrazine–water mixtures using the Tag open-cup method. (Graph created by Schmidt 2016, based on data from [629].)

Note: Data corrected for sea level conditions.

**Figure 34:** Effect of water dilution on the flash point of methylhydrazine. (Reproduced and modified from [630].)

Similar to the hydrazine flash point and fire point curve for anhydrous hydrazine, the flash and fire points coincide until the MMH concentration drops below 50% by weight and the two curves begin to diverge. Mixtures containing only 35 or 30% MMH were not ignitable at temperatures near the boiling point of water. The effect of water dilution on the flash point of MMH is shown in Figure 34. A similar chart exists for Ae-50.

## 10.2 Auto-Ignition Temperature of MMH in Air

The auto-ignition temperature of a fluid is the minimum temperature at which a combustible fluid with or without an oxidizer (usually air) spontaneously ignites and produces a flame. Auto-ignition temperature depends on the composition and pressure of the combustible vapor and on the type of hot surface present. It also depends on the amount of confinement, if the vessel is vented or not. Upward propagation in a gravity field aids ignition (the source of ignition is at the bottom of the test vessel). One method used for determination of self-ignition temperatures of combustible fluids uses the Setchkin apparatus. The auto-ignition temperature of MMH vapors in oxygen is about 100 K lower than that in air (Figure 35 and 36).

The auto-ignition temperatures of MMH and Aerozine-50 in air were tested at three pressures in an altitude-simulated auto-ignition test system (a 500-mL round-bottom borosilicate glass flask), as summarized in Table 41. MMH auto-ignition occurred over a narrow range of temperatures and did not show the wide scatter of data as did hydrazine. The auto-ignition temperatures of hydrazine, MMH, and UDMH in air and oxygen at atmospheric pressure in glass and steel vessels are summarized in Table 42.

**Figure 35:** Auto-ignition temperature of methylhydrazine in air. (Reproduced and modified from [90].)

**Figure 36:** Auto-ignition temperature of methylhydrazine in oxygen. (Reproduced and modified from [90].)

**Table 41:** Auto-ignition of methylhydrazine/air and Aerozine-50/air mixtures.

| Pressure           |      | Temperature |     |
|--------------------|------|-------------|-----|
| kPa                | psia | K           | °F  |
| <i>MMH</i>         |      |             |     |
| 85.5               | 12.4 | 468         | 382 |
| 48.2               | 7.0  | 470         | 386 |
| 10.3               | 1.5  | 474         | 393 |
| <i>Aerozine-50</i> |      |             |     |
| 85.5               | 12.4 | 458         | 365 |
| 31.0               | 4.5  | 463         | 374 |
| 5.2                | 0.75 | 468         | 383 |

Note: All Temperatures in K; Data in *italics* are interpolated

Data source: [632]

The same two vessels were used to measure the effect of initial pressure on the auto-ignition temperature of hydrazine, MMH, and UDMH. The results are summarized in Table 43.

A CRES-304 chamber measuring 15.7 cm in diameter and 14.7 cm high was used to study the pressure dependence of the auto-ignition temperature of MMH in air at 20–100 kPa [633]. The chamber pressure was adjusted to the desired pressure by evacuation. The chamber was heated prior to injection of the fuel sample. The fuel sample was temperature conditioned to 322 K prior to injection. Photocells, thermocouples, and pressure transducers were used to sense the reaction. The test sequence was such that MMH was injected into the test chamber, which had been preconditioned. If auto-ignition occurred, then the same quantity of fuel was injected for a subsequent test at a temperature that was 10 °F lower than before. The process was repeated until the lowest auto-ignition level for temperature, pressure, and amount of hydrazine injected was verified. In two test series with hydrazines in air at four different pressures, this required 336 individual tests for MMH [634]. For comparison, the ignition delay of hydrazine in air varied from 0.5 to 27 s. The ignition of MMH was more sluggish and the ignition delay varied from 1 to 82 s. The auto-ignition temperature of MMH was lower than that of hydrazine under all test conditions. For MMH, it decreased from 500 to 450 K when the pressure was increased from 20 to 100 kPa. For hydrazine it decreased from 488 to 400 K over the same pressure range. In both cases, measured overpressure agreed closely with that predicted for a deflagration and was far lower than what would have to be expected if a detonation had occurred. No ignitions were observed at pressures below 6.5 kPa. For MMH, the lowest pressure at which an auto-ignition was obtained was 20.6 kPa at a temperature of 488 K. An older publication listed the auto-ignition temperature of MMH in air as 469 K [1].

### 10.3 Auto-Ignition Temperature of MMH in Other Atmospheres

A study similar to an earlier study on self-heating and spontaneous heating of hydrazine investigated the self-heating and spontaneous ignition in the combustion and oxygen-free decomposition of MMH [510]. The combustion according to:

is exothermic with  $-1340 \text{ kJ/mol}$  ( $-320 \text{ kcal/mol}$ ). The critical conditions of pressure, temperature, diluents, and oxidizer–fuel ratio leading to ignition were examined in this investigation. Uncommon among gas-phase reactions, the combustion of MMH was dominated by thermal effects, and no obvious symptoms of radical chain branching kinetics could be detected. The technique used in this experiment consisted of pre-mixing MMH and oxygen at ambient temperature and admitting it to a heated, evacuated vessel while simultaneously recording temperature and pressure until ignition occurred. A thermocouple in the center of the vessel would frequently read temperatures higher than the wall temperature before ignition occurred, indicating a self-heating mechanism preceding actual ignition. An activation energy for the  $\text{O}_2$ –MMH reaction was derived from the slope of a  $\ln(P_c/T_a^2)$  versus  $1/T_a$  curve, where  $P_c$  was the critical pressure at which ignition occurred and  $T_a$  was the initial temperature of the Pyrex vessel. The calculated activation energy for MMH was  $80 \text{ kJ/mol}$  ( $19.1 \text{ kcal/mol}$ ), which compares with  $101 \text{ kJ/mol}$  for hydrazine itself and  $67.3 \text{ kJ/mol}$  for UDMH. In evaluating the effect of diluent gases on the pressure required for ignition, helium dilution required a higher pressure, nitrogen dilution had little effect and argon and krypton dilution lowered the pressure down to which ignition could be achieved (Figure 37).

The auto-ignition flammability characteristics of hydrazine fuels in  $\text{NO}_2$  atmospheres was investigated at the US Bureau of Mines [630, 632, 635]. Minimum auto-ignition temperatures were determined at various pressures from 3.3 to 98.6 kPa (25 to 740 mm Hg) for hydrazine, MMH and UDMH in air, oxygen, and nitrogen dioxide with either nitrogen or helium diluents. Lower auto-ignition temperatures were obtained in nitrogen dioxide (coming from dinitrogen tetroxide) than in oxygen. Generally, the AIT values for most of the combustibles increased slightly with decreased pressure and oxidant concentration to some critical value, and then they tended to increase noticeably. They also varied with the size of the reaction vessel. The spontaneous ignition temperatures (S.I.T.) of air/MMH vapor mixtures and air/UDMH vapor mixtures in contact with 100 percent  $\text{NO}_2$  were determined in the I-8 apparatus. These tests were conducted in the same manner as described previously. The results of these tests are shown in Figure 38. These results showed that for the same combustible concentrations the MMH had lower S.I.T.'s than did UDMH up to a concentration of 6.8 percent combustible; above this concentration the reverse was true. A similar phenomenon was observed for the S.I.T.'s of the liquids when they were injected into  $\text{NO}_2$ -air atmospheres. Further S.I.T. tests were conducted with these combustibles using mixtures of  $\text{NO}_2$  and air as the oxidizing atmosphere in place of the pure  $\text{NO}_2$ . The results of these

**Figure 37:** Effect of dilution on critical partial pressure  $p(\text{O}_2) + p(\text{MMH})$  in mixtures  $\text{MMH} + 2\text{O}_2 + \text{diluent X}$  at 703 K as a function of percentage diluent X added. (Republished and modified from [510], with permission of ©1974 Royal Society of Chemistry; permission conveyed through Copyright Clearance Center Inc.)

tests using two different  $\text{NO}_2$ -air mixtures (50 volume-percent  $\text{NO}_2$  and 10 percent  $\text{NO}_2$ ) are shown in Figure 38 for MMH and a similar image for UDMH in chapter “Dimethylhydrazines” of this volume, the *Encyclopedia of Liquid Fuels*.

Measuring the spontaneous ignition temperature of MMH as a function of  $\text{NO}_2$  concentration in air, and varying the temperature of the injected liquid, it appears that one specific MMH temperature (309 K) resulted in the most sensitive ignition situations. The technique used was to inject small amounts (70  $\mu\text{L}$ ) of fuel into a uniformly heated 250- $\text{cm}^3$  borosilicate glass Erlenmeyer flask containing air and  $\text{NO}_2$ . Under these conditions, hydrazine itself was more difficult to ignite than methylhydrazines. With increasing ambient temperature, ignition occurred at lower and lower  $\text{NO}_2$  concentrations, as shown in Figure 38 for MMH. Helium dilution narrowed the auto-ignition range, and pressure increase widened it.

The data (taken from different USBM reports) in Figure 38 (above) and Figure 39 (below) represent similar conditions leading to spontaneous ignition of MMH liquid in  $\text{NO}_2$ /air mixtures at 298 K. The asterisk on  $\text{NO}_2^*$  is supposed to indicate that this is an equilibrium mixture of  $\text{NO}_2$  and  $\text{N}_2\text{O}_4$  in the vapor state.

**Figure 38:** Minimum spontaneous ignition temperatures of liquid methylhydrazine at various initial temperatures in  $\text{NO}_2$ -air mixtures as a function of  $\text{NO}_2$  concentration. (Reproduced and modified from [90], as adapted from [635].)

**Figure 39:** Spontaneous ignition temperature of methylhydrazine in  $\text{NO}_2$ /air mixtures at 298 K as a function of MMH concentration. (Reproduced and modified from [630].)

Kinetic models derived for the  $\text{NO}_2/\text{N}_2\text{O}_4$  and MMH vapor reaction were confirmed by measuring the ignition boundaries of  $\text{NO}_2/\text{N}_2\text{O}_4$  and MMH vapor as a function of helium dilution, mixture ratio, and pressure at room temperature [329]. The ignition of  $\text{NO}_2$  and MMH vapors diluted in helium was measured for gas–vapor mixtures containing 20, 30, 40, or 47% propellant in helium. The results for the 47% mixtures are shown in Figure 40. Note that the limit is offset toward fuel-rich mixtures. This offset became more visible with higher dilutions.

**Figure 40:** Dinitrogen tetroxide/methylhydrazine vapor flammability diagram at room temperature (295 K). (Republished and modified from [329], with permission of ©2006 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

The minimum pressure for ignition as a function of mixture ratio showed a minimum at equivalence ratios of 1.0 for He mixtures with 20–30% propellants, 1.5 for 40%, and 2.0 for 47% propellants. This type of laboratory study with vapor-phase reactions is of interest for explaining ignition delays with liquid–liquid reactions in rocket engines.

#### 10.4 Flammable Range of MMH Vapors in Air

The limits of flammability of combustible vapors and gases depend on composition, temperature, pressure, mode of initiation, geometry of vapor space, and the direction of propagation [636, 637]. It is impossible to discuss here all these parameters in de-

tail, mainly because they have not yet been determined in such detail for hydrazine and MMH. Most of the hydrazine(s) work was done for limits of flammability in air, but some information is also available for other oxidizing atmospheres (oxygen, nitric oxide, nitrogen dioxide) or in dilution with inerting compounds (nitrogen, heptane, water). Because the methylhydrazines are more volatile than hydrazine, there is more concern about forming flammable mixtures with these fuels than with hydrazine itself.

To evaluate the potential fire hazard of MMH and UDMH and compare it with that of better known flammable fluids already in use (e.g., gasoline), the following properties are examined here: limits of flammability, auto-ignition temperature, flash point, and minimum required ignition energy. A comparative hazard evaluation must be based on a consistent set of data, all obtained with the same method. The results of flammability or auto-ignition of one and the same compound will vary widely depending on the method and the apparatus used. It would be desirable for all investigators to use standardized flammability test methods. Unfortunately, only the flash-point procedure is covered by an ASTM standard (ASTM D98). For the other fire hazard properties, there exist no standard procedures applicable to MMH, and the results vary from investigator to investigator, depending on the method used, making a comparison very difficult. Most data on flammability characteristics of combustible gases, and vapors other than hydrazines were obtained by the US Bureau of Mines (USBM) using a setup that has become known as the USBM Flammability Tester [636]. Results obtained with this apparatus are considered reliable, but are typically obtained only for gases and vapors at room temperature. The flammable ranges of hydrazine and its methyl derivatives shown in Figure 41 are superimposed on vapor pressure curves, even though the actual flammability testing was conducted at higher temperatures.

The flammability limits of MMH in air are 2.5% by volume (lower limit) and  $97 \pm 2\%$  (upper limit), as reported by an MMH manufacturer, but the type of apparatus was not stated, and obviously 97% MMH in air can only be reached at elevated temperatures [1].

Reducing the pressure below sea-level pressure narrows the flammability range. As the pressure decreases, the two flammability limits approach each other until they merge at a point where no flame propagation is possible. This is the lower pressure limit of flammability, regardless of the composition of the flammable mix. The low pressure limit is still dependent on the ignition energy and the dimensions of the test apparatus.

The ignition limits of hydrazine/air and MMH/air mixtures at reduced pressures were measured in a 2-L CRES-304 chamber measuring 15 cm in diameter without provisions for stirring the gas-vapor mix [631, 633, 638]. A 750-mJ spark jumping a 3.2-mm gap was used to initiate the mixtures. A capacitor bank delivered approximately 1J within 2ms. Overpressure data from the closed vessel indicated that all mixtures merely deflagrated rather than detonated. For anhydrous hydrazine, the flammable range narrowed as the pressure decreased, until below 4 kPa partial

**Figure 41:** Flammability range of hydrazine, methylhydrazine, and unsymmetrical dimethylhydrazine in air. (Reproduced and modified from [637].)

pressure no ignition occurs at any of the several mixture ratios tested. Similar tests were performed with MMH. In this apparatus, in the absence of air, a 1-J spark did not ignite pure MMH vapor at the boiling point of MMH (360.8 K). Temperature had little effect on the lower limit of flammability of unsaturated MMH vapor in air. For MMH in air, the lowest pressure for flammability was 3.1 kPa (0.45 psia) with a mixture containing 7.7% MMH. At 366 K, the lower limit is at 2.8 vol-% MMH and the upper limit is at 95.7% MMH as shown in Figure 42 [627].

Similar tests with MMH gave positive ignitions within the entire range tested down to 7 kPa. The minimum ignition pressure of air/MMH was observed at 3.14 kPa with an MMH concentration of 7.7% by volume. No ignition was obtained in 100% MMH vapor anywhere below 100 kPa. The flammability curve (flammable range boundary plotted in a pressure versus % by volume MMH graph) showed an unusual double-lobed

**Figure 42:** Flammability limits above liquid methylhydrazine in air as a function of temperature and pressure. (Reproduced and modified from [90] based on [627].)

shape, which has not yet been explained. Graphing these data for just two temperatures with only the lower and upper limits shown gives a curve that has an unusual sinusoidal undulation in the range between 25 and 50% MMH (Figure 43).

Methylhydrazine is more flammable than hydrazine. Flammability in the vapor phase as tested in the NASA apparatus was effectively suppressed by adding 25% by volume water to MMH at 300 K.

**Figure 43:** Effect of pressure on the limits of flammability of methylhydrazine in air. (Reproduced and modified from [627])

## 10.5 Card Gap Sensitivity of MMH and MMH Mixtures

The card gap sensitivity of MMH/N<sub>2</sub>H<sub>4</sub>/HN mixtures is shown in Figure 50 in Section 13.3.5.2 on MMH fuel blends. As can be seen from this graph, MMH at the corner is safely distanced from the boundary of detonable mixtures in this ternary system. MMH is not detonable at zero cards.

## 10.6 Electrostatic Discharge Sensitivity of MMH

The minimum ignition energy of 2.9 vol.-% MMH vapor in air was 2.9–3.4 mJ, as determined in a flow-through system that was better suited to high boiling liquids than the static ASTM system [639]. Designers for propellant storage and transfer facilities should adhere to the recommendations provided in National Fire Protection Association 77 *Static Electricity* [640].

## 10.7 MMH Decomposition in Proximity to Pyrovalves

Mars Observer was lost shortly after sets of pyrovalves had been fired in preparation for the arrival at Mars. Although a different scenario involving oxidizer permeation through the Teflon seats of check valves was a more likely cause of the accident, safety testing of MMH reactions in pyrovalves with and without blowby was part of the Mars Observer investigation [641–644]. After two earth satellites were lost due to blowby from pyrovalves igniting hydrazine (not MMH), the sensitivity of MMH exposed to hot blowby products of an actuated pyrovalve was also experimentally evaluated using both a pyrovalve simulator and commercial pyrovalves in test configurations simulating a MMH-based propulsion system. Additional testing at NASA WSTF looked at the hazard potential of MMH decomposition initiated by pyrovalve blowby, in this case as part of the Space Station Interim Control Module (ICM) propulsion system safety evaluation. This involved propellant lines with substantial outer diameters of 19 mm (¾ in). The propulsion system developed by NRL was at one time planned to be used as an Interim Control Module on the International Space Station (ISS) in case the Russian Zvezda service module was not delivered on time. The influence of pyrovalve blowby was a serious concern during system development because of earlier incidents where two satellites were lost owing to pyrovalve interaction with anhydrous hydrazine. By comparison with results of previous pyrovalve simulator tests using water to establish water-hammer effects and tests using the more reactive hydrazine, MMH was found to be insensitive to blowby in all tests performed. Specifically, test results showed no evidence that the blowby caused a self-sustaining, exothermic decomposition event with MMH in three pyrovalve simulator tests, an ICM MMH tank outlet configuration test, or two ICM MMH tank inlet configuration tests. MMH did not undergo explosive decom-

position under test conditions in identical hardware, which had previously resulted in destructive reactions with anhydrous hydrazine  $\text{N}_2\text{H}_4$  as part of the LANDSAT-F and TELSTAR-402 failure investigations.

### 10.8 Detonability of MMH Vapors

MMH vapor diluted with argon was decomposed in a 38.4-mm i.d. shock tube behind a reflected shock wave at 1040–1370 K, 140–455 kPa, and in mixtures containing 97 to 99 mol-% argon, and the kinetic rate data obtained from experiments with argon-diluted MMH were used to predict the detonability of undiluted MMH vapor [645]. The computer model predicted that MMH vapors are much less susceptible to detonation than hydrazine vapors. The predicted detonation cell diameter was large in relation to the tube diameter used in this study.

The same equipment was also used for studying the detonation of  $\text{O}_2$ /MMH vapor/ $\text{N}_2$  mixtures initiated by an incident shock wave [292]. The detonation velocity of mixtures consisting of 52.4 mol-%  $\text{O}_2$ /47.6% MMH (equivalence ratio  $\phi = 2.27 = \text{fuelrich}$ ) at an initial pressure of 2 kPa was 2400 m/s. This value was below that predicted from C-J calculations for this mix.

The structure of shock waves and the conditions conducive to detonation of hydrazine, MMH and UDMH by themselves or in  $\text{Ar}/\text{O}_2$  mixtures were analyzed in order to determine criteria for the detonability limits [646]. Under these conditions, hydrazine and MMH were pyrolyzed and UDMH was oxidized behind a shock wave to determine the induction periods.

There is continued concern about the explosive decomposition of residual MMH in propellant tanks of expendable or reusable space transport vehicles returning from orbit and re-entering the atmosphere. The concern is that an explosion of the MMH tank might propel fragments into low orbits occupied by other satellites. Similar concerns had been expressed earlier about anhydrous hydrazine tanks left uncontrolled in orbit (such as those on the PEGASUS HPU upper stages) or re-entering at the end of a mission.

The European Automated Transfer Vehicle (ATV) was a supply cargo vehicle for the ISS. The European Automated Transfer Vehicle and the US DRAGON both use NTO/MMH for attitude control and orbit adjustment, reentering with partially filled MMH tanks. The ATV is expendable and designed to burn up during re-entry in unpopulated areas. In contrast to the ATV, the Space-X CARGO DRAGON and CREW DRAGON are reusable, but they re-enter without their service module. There is concern that explosions of the propellant tanks in the ATV or the service module will change the footprint of where parts may splash into the ocean if they do not completely burn up in the atmosphere [647–649]. Visual observations of the breakup of the ATV JULES VERNE during its re-entry into the atmosphere indicated that the breakup was actually different from what computations had predicted [650]. The

ATV carried MMH for its own consumption and UDMH as cargo for resupply for the ZVEZDA service module on the ISS. When the supply ship undocked from the ISS, and after the re-entry burn, there were 135 and 144 kg of MMH remaining in the two fuel tanks. There were also 260 and 277 kg of MON remaining in the two oxidizer tanks. Therefore, a total of 819 kg of available propellants were capable of igniting with each other or with hot air from the re-entry aerobraking. The tanks might rupture owing to simple overheating and vapor pressure buildup, or owing to MMH decomposition. The overheating seems to be more probable. The first explosion occurred at an altitude estimated at 75 km. This event caused the disintegration of the vehicle into several fragments. A second explosion occurred 35 s after the main explosion. This event happened in one of the main fragments produced by the initial vehicle disintegration. The spacecraft also had lithium ion batteries on board. The scenario with the first explosion initiated by MMH decomposition is the most probable as lithium emission lines in the spectrum from the explosion started showing up only with a delay of 5 s.

A computational analysis of the re-entry heating of the ATV examined the ignition and explosion potential of MMH/NTO, UDMH/NTO, and MMH with atomic oxygen from the re-entry plasma [651, 652]. The simulations examined the internal flow field, which is at chemical equilibrium with a low fraction of atomic oxygen. The temperature and oxygen partial pressure were not high in the middle of the vehicle: of the order of 1300 K and 50 Pa. Close to the walls, particularly on the top part of a fissure, the heat-flux and the pressure were very high: 500 kW/m<sup>2</sup> and 1950 Pa. The temperature rose up to 3000 K, a level high enough to start the dissociation of diatomic oxygen. Its partial pressure reached a level of 500 Pa. This part of the ATV is very close to the location of propellant tanks, which could be damaged by the local high levels of heat flux and temperature. However, the predictions showed a high level of diatomic oxygen in the whole vehicle and the explosion analysis established that this species is the best candidate to ignite a chemical reaction in the space surrounding the tanks. This is due to a partial pressure more than one order of magnitude higher than the minimum ignition pressure. These computational results predicted a high risk of explosion if the propellants enter in contact with the internal flow.

## 10.9 Adiabatic Compression Sensitivity of MMH

Most other monopropellants, in particular organic nitro compounds and nitrate esters, are known to be sensitive to adiabatic (i.e., isentropic) compression. With those compounds, the sudden temperature increase in a collapsing bubble is sufficient to initiate detonation and, at the same time, additional bubbles provide a mechanism for propagation of LVD. A monopropellant of that type that has not been thoroughly degassed or is even filled with bubbles from transportation vibrations/sloshing or transfer from one container to another propagates LVD once a source of initiation is present. In contrast, liquid bulk MMH could not be initiated to detonation by rapid or adia-

batic compression. An adiabatic compression sensitivity study conducted at Aerojet measured four fuels (hydrazine, MMH, MHF-5, and MHF-7) in contact with 11 metallic materials of construction [247]. The U-tube apparatus used for these experiments has subsequently been adapted for safety investigations by several other research groups. It consisted of a tube measuring 6.35 mm (0.25 in.) in O.D. bent to the shape of a U 152 mm (6 in.) high and closed on one end by a plug. The propellant sample (3 mL) filled only the lower one-tenth of the nitrogen-filled tube. The entire assembly could be lowered by remote control into a temperature-controlled bath prior to the test. The upstream end could be rapidly pressurized with nitrogen by using a fast-acting valve and a burst disk at a rate of 2064 MPa/s (300000 psi/s). Positive tests were indicated by burst or bulged tubes. Neither MMH nor MHF-7 was sensitive to adiabatic compression up to temperatures of 533 K (500 °F). Hydrazine vapor was the most sensitive compound tested; MMH vapor was able to desensitize hydrazine vapor. In the U-tube test series at Aerojet, none of the 35 tubes from 10 different metals tested at four different compression rates and temperatures up to 540 K (512 °F) with MMH exploded.

In trying to predict the temperature rise as the result of adiabatic, isentropic compression from theoretical calculations, previous work had validated the SRK EOS for computing isentropic compression temperatures for MMH vapor [94]. That work showed a significant difference between treating MMH as a real fluid and as an ideal gas. Isentropic compression or expansion of two-phase mixtures, e.g., liquid/vapor, of MMH. This analysis included re-evaluation of the published low-temperature vapor pressure correlation and recalculation of a pseudo-Mollier diagram,  $\ln(T)$  vs.  $S$ , for saturated liquid and saturated vapor using integration of the orthobaric heat capacity, demonstrating the usefulness of this pseudo-Mollier diagram.

#### **10.10 Water (Fluid) Hammer and Surge Flow Conditions Conducive to Rapid Compression Events in MMH**

Hydrazine has a lower compressibility than MMH or water and therefore is more likely to encounter pressure spikes where water hammer or surge flow conditions are encountered. Although there is less concern about MMH causing problems of the type observed with anhydrous hydrazine, fluid hammer and surge flow pressure spikes with MMH have been measured and predicted by fluid dynamic computer models. Most of the computer models described here are not unique to MMH and can be applied to flow properties of other propellants as well.

Several publications deal with the manifold filling (“priming”) and water hammer fluid dynamic aspects of bipropellant systems, many of those using MMH as the bipropellant fuel. Although there is less concern about MMH undergoing explosions caused by “adiabatic” rapid compression, these data should be summarized here nevertheless. In many cases, the analytical computational methods used to model the fluid dynamics of bipropellants can be applied to calculating the behavior of hydrazine

in monopropellant feed systems. Experimental techniques for determining the safety threshold of water hammer and surge flow in bipropellant systems can be equally well used for examining hydrazine monopropellant systems.

Startup hydraulic transients in a feed system dropping MMH from a reservoir at 10 MPa into an evacuated U-shaped tube section were calculated, including bending forces exerted on the U-tube while the liquid front is rushing at 50 m/s through the bend, suddenly changing direction [653]. It appears that forces exerted by the liquid flow were at one time sufficient to rupture weak weld sections when the lines were not properly tied down (this event is not described in detail). It was recommended to firmly clamp the tubing to make it immovable to eliminate stresses on the welded section. There is no chemical reaction involved in bending these tubes. It is a strictly mechanical phenomenon.

A simplified model was derived to describe the flow of MMH (and NTO) into evacuated and pressurized straight lines, which allows prediction of peak pressures [654]. The following simplifying assumptions were made in this model:

- Gas solubility in liquid propellant is negligible.
- Vapor formed by propellant evaporation is negligible in comparison with the amount of pressurant gas in the line.
- Owing to high shock speeds (helium) the gas is everywhere at the same pressure.
- Gas behaves adiabatically.
- Propellant lines are rigid.

Valve opening times had only a slight effect on the pressure history for pressurized lines. Calculated peak pressures were greatest for downstream line lengths of 30 to 60 cm. MMH, a less dense liquid than NTO, attains higher flow velocity in the evacuated line and higher impact pressures. If one attempts to equalize the peak pressures, the MMH line should be made a little longer than the NTO line. Longer upstream lines between the propellant tank and the isolation valve also reduce the pressure spikes.

Shuttle-launched payloads required three inhibits to prevent accidental propellant leakage into the payload bay. For a typical Shuttle-launched satellite there were a pyrovalve, a latching valve, and the thruster control valve. Testing of a satellite bipropellant propulsion subsystem manifold with water as the reference fluid was conducted to measure pressure spikes at the latch valve after opening the pyrovalve [655, 656]. There was concern that the impact of the surge flow on the closed latch valve might damage the valve seat or flip the valve open. Tests were conducted with gas-filled and evacuated straight tube sections and with branched flow passages. It was concluded that surge pressure spikes due to quick priming rates of pyrovalves (opening times ~3 ms) are not any worse than those caused by opening electromagnetic latch valves (opening times ~25 ms). Friction in the trunk feed line greatly reduces the potential for surge pressure spikes in the branch lines.

A more detailed model was used to describe feed system transients in the aft propulsion subsystem of the Space Shuttle, a bipropellant system housed in two pods

containing the Orbit Maneuvering System (OMS) and the Aft Reaction Control Subsystem (ARCS) [657]. The line diameters in this system range all the way from 38 to 6 mm. Water hammer pressure spikes resulting from engine shutdown and sudden valve closings were significant and needed to be limited to prevent damage to instrumentation and valves. A replica of the feed system was built for hot engine firings of the all-up propulsion subsystem on the ground. Different duty cycles were simulated, which required two or more valves to close simultaneously and the resulting pressure spikes were recorded. The actual system was more compliant than predicted. Tests were conducted with both helium-saturated and unsaturated propellants. The worst pressure spikes ( $10.9 \text{ MPa} = 1588 \text{ psi}$ ) were caused by firing three thrusters in-synch simultaneously for a 0.08 s on/0.08 s off duty cycle.

A similar method of characteristics model called Liquid Rocket Transient Code was applied to the main engines of the TITAN-4 launch vehicle [658]. Modeling of this system was complicated by the presence of accumulators, which serve to suppress pogo problems. All studies referenced above dealt with flow into or against closed, dead-ended cavities. A slightly different situation exists with injector manifolds in bipropellant thrusters filling with propellant at the start and draining propellant at the end of each pulse. Here, the start-up flow impinges on a narrow but open injector bore at the end of the line. The thrust build-up and decay portions of each thrust-time curve represent the major unknown and depend on the injector filling time and the injector draining time (emptying the dribble volume). Impulse bit reproducibility of bipropellant thrusters is important, but varies with altitude if bipropellant thrusters are used for RCS or roll control of launch vehicles as they leave or re-enter the atmosphere. Experiments with injector manifolds in a vacuum chamber were conducted with water and fluorocarbon F-12 as inert substitutes for hypergolic propellants [659]. Analytical equations were derived to predict manifold filling times for different operating conditions and injector geometries. This information is useful for the systems designer as well as the rocket engine designer.

The attitude control system of the planned European space plane HERMES was planned to be similar to that of the Space Shuttle. The pressure-fed NTO/MMH system would have been similar to that of satellites, but more complex as it also had to serve deorbit maneuvers and operate during atmospheric re-entry. A method-of-characteristics code named SIR-3S based on an existing code similar to Hytrap was used to model water hammer dynamics of the HERMES ACS system [660]. The propellant distribution system manifold was feeding propellant to 400-N and 10-N thrusters. Two of the high- and two of the low-thrust REAs may operate in pulse mode and close simultaneously, resulting in pressure waves propagating upstream in the system. The pressure fluctuations may cause mixture ratio shifts that reduce the thrust to 50% of nominal thrust. It was also attempted to determine the natural frequency of the plumbing system, dependent on the line length and tubing wall material.

Experimental test results of surge flow with water in simplified straight and 90° bent line geometries were compared with numerical simulations computed for MON,

MMH, or water using ANABEL software [661]. This computer program can perform computations of transient compressible/uncompressible monophasic or diphasic flows with separated phases in fluidic networks, allowing the prediction of water hammer and also pressure losses. With a push pressure of 40 bar, the predicted pressure spikes at the end of the line were 172 bar for MMH, 200 bar for MON and 183 bar for water.

A comparison was made between thermal demonstration test results and dynamic simulation of water hammer effects resulting from activation of fast-acting isolation valves in the flight-like system of the Japanese HTV propulsion system [662]. The objective was to reduce surge pressures associated with manifold activation of on-orbit vehicles utilizing rapid-response isolation valves.

Fluid hammer experiments were conducted with MMH, NTO, or water in the Propulsion Laboratory of Office National d'Etudes et de Recherches Aérospatiales (the French aerospace lab) [663]. The objective of that study was to generate a reliable experimental database on the fluid hammer phenomenon with real propellants (MMH and NTO) to validate the physical models implemented in the numerical codes. This database with real propellants extended the database obtained by the von Karman Institute on surrogate fluids (water, ethanol, and acetaldehyde). For each real propellant, experiments were performed for a vacuum pressure in the propellant line below and above the saturation pressure of the fluid to highlight the influence of the physical phenomena encountered (vaporization, cavitation) on the fluid hammer. With MMH, fluid hammer frequency and amplitude decreased for increased vacuum pressure. Only one experiment was performed with NTO for a vacuum pipe pressure below the saturation pressure. Compared with MMH and water experiments performed under the same operating conditions, the fluid hammer amplitude and frequency with NTO were smaller. Regarding the peak temperature in the gas pocket, very small variations were recorded for water and MMH whereas the temperature increase for NTO was more than 350 °C.

Rapid closing of a propellant valve shutting off a flow of MMH may cause pressure spikes by water hammer, and such pressure spikes may near-adiabatically compress bubbles of MMH vapor trapped in other parts of the system. MMH was not sensitive to water hammer pressure spikes [664].

## 11 Toxicity of MMH

In the following, the emphasis is on providing all necessary information on the safe handling and toxicity of MMH. In many cases, publications do not deal with just MMH by itself, but also look at the toxicity of MMH in comparison with other hydrazines. Consequently, this chapter contains some information on hydrazine  $N_2H_4$  and UDMH in addition to the info on MMH, and duplication with information provided in other chapters on hydrazine  $N_2H_4$  and UDMH is unavoidable.

When comparing molecular structures of hydrazine, MMH, and UDMH, MMH seems to take an intermediate position when it comes to counting the number of methyl substituent groups. However, this is not the case when comparing the toxicity of the three hydrazines. With most of the methods of administration of MMH in animal exposure tests, MMH is more toxic than either of the other two hydrazines [665, 666].

For discussion of possible adverse effects of MMH in an occupational environment, two types of inadvertent exposure have to be mainly considered: vapor inhalation or liquid splashes. The first type of exposure would cause predominantly respiratory and systemic effects, whereas in the latter case skin effects and eye effects must be considered in addition to respiratory and systemic effects. Accidental oral ingestion does happen, but is less likely and is readily diagnosed.

There are a few valuable review articles and summaries on hydrazine(s) toxicity such as Toth 1988 with 326 references [667], Moloney 1983 with 200 references [668], and Choudhary and Hansen 1998 with 131 references [669]. Many toxicity reviews have included SDMH (which is not used as a rocket propellant and is used in small quantities only for laboratory toxicity tests) but have omitted the practically more important MMH.

The US Air Force, as one of the main users of propellant hydrazines, has conducted a long series of toxicity studies and published the results in a series of reports which are summarized in a bibliography [670]. When comparing the inhalation hazard potential of MMH with that of the other hydrazines, not only the toxicity (often expressed as lethal concentration 50 [LC50], that is, the concentration at which 50% of a statistically significant number of test animals perished within a specified observation period) but also the vapor pressure factors in on the handling hazard. The quotient of vapor pressure divided by LC50 (in arbitrary units) is called the *Hazard Index*. Table 44 gives a comparison of the hazard indices of the three propellant hydrazines, also in comparison with the oxidizer NTO, which is usually also present in all installations where MMH is used as a fuel.

**Table 44:** Hazard indices of hydrazine and methylhydrazines.

| Compound                           | Formula                                          | Vapor pressure at 298 K<br>(25 °C = 77 °F), mm Hg | LC50, 4 h,<br>ppm | Hazard index,<br>mm Hg/ppm |
|------------------------------------|--------------------------------------------------|---------------------------------------------------|-------------------|----------------------------|
| Hydrazine                          | N <sub>2</sub> H <sub>4</sub>                    | 14.4                                              | 570               | 0.03                       |
| Methylhydrazine                    | CH <sub>3</sub> NHNH <sub>2</sub>                | 49.6                                              | 74                | 0.67                       |
| Unsymmetrical<br>dimethylhydrazine | (CH <sub>3</sub> ) <sub>2</sub> NNH <sub>2</sub> | 156.8                                             | 252               | 0.62                       |
| For comparison:                    |                                                  |                                                   |                   |                            |
| Dinitrogen tetroxide               | N <sub>2</sub> O <sub>4</sub>                    | 875                                               | 67                | 13                         |

Data source: [671]

The following individual subsections are subdivided by the part of the body affected. As with many other toxic substances, the response may be species-dependent or even strain-dependent; for instance, MMH may cause cancer in one species of test animal, but not in another.

Exposure to acute doses of MMH can cause a variety of symptoms and pathological changes depending on the concentration of MMH and the animal species. Symptoms include diarrhea, emesis, salivation, irritation of mucous membranes, dyspnea, and convulsions. At lethal doses, cause of death is usually respiratory depression. Findings at necropsy on dogs and monkeys exposed to lethal and near-lethal levels of MMH are variable but may include pulmonary congestion with hemorrhage, hepatic congestion, and kidney damage ranging in severity from mild swelling of the renal tubular epithelium to vacuolization and coagulative necrosis of these cells. The range between a lethal or near-lethal concentration of MMH, producing major or pathological changes and overt symptoms, and a concentration having minimal effect is very narrow; the dose–response curve is extremely steep.

One of the prime target organs of poisoning by hydrazine and hydrazine derivatives is the liver. Symptoms include fatty degeneration of liver tissue, centrilobular damage, changes in glycogen content, and loss of mitochondrial activity. In the blood, MMH causes hemolytic anemia, methemoglobinemia, hypoglycemia, and Heinz body formation. It affects the coagulation mechanism. Numerous enzymes are disturbed by the presence of hydrazines. The metabolic pathway of hydrazines can be traced by a number of experimental techniques that help to explain the observed symptoms. Symptoms in the kidney and urinary tract that were caused by hydrazine(s) included changes in creatinine clearance and rate of glucose resorption. Other symptoms caused by hydrazine, MMH, or UDMH included increased salivation, hyperventilation, vomiting, diarrhea, and increased neuromuscular activity (spasms). Because MMH is an amino compound, it interferes quite actively with amino acid chemistry in the body, in particular protein metabolism.

### 11.1 Inhalation Toxicity of MMH

This section contains a summary of acute toxicity studies with experimental animals. Most of these studies were done for inhalation toxicity of MMH, which was expected to be the most likely mode of accidental entry of poisons into the body for accidents with humans in places where MMH is manufactured and used.

The use of rodent whole-body exposure data to set TLVs for exposure of humans at the work place has been criticized, but there are no other generally accepted methods to determine safety data. It has been argued that the rodents often lick themselves and that they absorb more hydrazine by ingestion than inhalation. This would not be the case for humans.

Unfortunately, of all modes of administration in animal tests, controlled inhalation concentration levels are the ones most difficult to maintain in an animal experiment because hydrazines are so reactive and may autoxidize in the air of the exposure chamber or may be absorbed by the fur of the animals or the bedding materials in the cage. In some instances, 96–99% of hydrazine metered into the air stream was decomposed or adsorbed after a single pass through the exposure chamber with or without dead or living animals in it. There is typically more scatter and less confidence in inhalation data than those obtained with other modes of administration, such as injection.

The data are analyzed using statistical methods, typically a probit plot, in the dose–response relationship, from which then a lethal concentration 50 (LC50) or lethal dose 50 (LD50) can be derived. This number indicates the concentration or dose at which 50% of the animals in an exposed group survive after a stated observation period. Quite often, investigators report the duration of exposure, but fail to specify the post-exposure observation period within which fatalities are counted.

#### 11.1.1 Short-Term (Acute) Inhalation Toxicity of MMH

Table 45 is a summary of exposure conditions for MMH inhalation acute toxicity tests.

**Table 45:** Methylhydrazine inhalation animal acute toxicity tests for determination of LC50.

| LC50, ppm | Exposure frequency, h/day | Total duration  | Test animal |
|-----------|---------------------------|-----------------|-------------|
| 74        | 4                         | Single exposure | Rat         |
| 56        | 4                         | Single exposure | Mouse       |
| 143       | 4                         | Single exposure | Hamster     |

Data source: [672]

Examinations of organs from necropsied dogs, rats, and mice exposed to MMH or UDMH at acute toxic concentrations revealed no significant pathological changes [672]. However, in surviving dogs after MMH exposure, there was evidence of hemolysis of erythrocytes. In the group including hydrazine, MMH, UDMH, and SDMH, MMH was the most toxic of the vapors tested for acute toxicity, whereas hydrazine was the least toxic.

Rats, mice, beagle dogs, squirrel monkeys, and rhesus monkeys were exposed to various measured concentrations of MMH in air vapor for specified time periods [673, 674]. Rodents were exposed for 30-, 60-, 120-, and 240-min. periods; dogs and squirrel monkeys, for 15, 30, and 60 min., and rhesus monkeys for 60 min. only. The toxicity of MMH for the five animal species was defined by determinations of LC<sub>50</sub> values, pathology, observations of responses, measurements of body weight in rats and mice, and blood chemistry and hematology tests on dogs, and rhesus monkeys. Squirrel mon-

keys proved to be the most sensitive and rats the least sensitive to the lethal effects of MMH. MMH exposure produced definite but transient, hemolytic changes in dogs and, to a lesser extent, in rhesus monkeys. Male and female rhesus monkeys (three to five per group) and male squirrel monkeys (two to four per exposure group) were exposed to MMH vapor for 60 min (rhesus monkeys) and 15, 30, or 60 min (squirrel monkeys; Table 46).

**Table 46:** Lethality in non-human primates and dogs following inhalation exposure to methylhydrazine.

| Duration, min. | Species         | Exposure, ppm | Concentration × Time,<br>ppm × min | Mortality ratio |
|----------------|-----------------|---------------|------------------------------------|-----------------|

Data source: [674]

For the rhesus monkeys there were no deaths following a 60-min. exposure to a mean concentration of 160 ppm. For the rhesus monkeys, no deaths occurred during the exposure period. A 60-min. LC<sub>50</sub> of 162 ppm was calculated for the rhesus monkeys. For the squirrel monkeys, deaths occurred as early as 2 h post-exposure, although most deaths occurred between 10 and 24 h post-exposure. The 15-, 30-, and 60-min. LC<sub>50</sub> values for the squirrel monkeys were 340, 145, and 82 ppm respectively. In the same publication, the acute lethal toxicity of rats, groups of 10 that were exposed to MMH at 30, 60, 120, or 240 ppm for 30, 60, 120, or 240 min. resulted in 30-, 60-, 120-, and 240-min. LC<sub>50</sub> values of 427, 244, 127, and 78 ppm respectively. Groups of 20 male

ICR mice were exposed to a range of MMH concentrations for 30, 60, 120, or 240 min. and the LC50 values for 30-, 60-, 120-, and 240-min. exposures were 272, 122, 92, and 65 ppm respectively.

Groups of 10 male Syrian golden hamsters were exposed to MMH at concentrations of 460, 620, 810, 910, 1110, or 1380 ppm for 1 h followed by a 14-day observation period [675]. Immediate irritation of the eyes and nose followed by labored breathing and gasping were observed in all exposure groups. The onset of these signs appeared to be concentration-dependent; signs appeared more rapidly as the concentration increased. Coordination was affected, although the hamsters did not become prostrate. Convulsions were observed during the last few minutes of exposure in hamsters of the highest exposure group. These convulsions continued as long as 1 h post-exposure. Hamsters that died did so within 24 h post-exposure, and all survivors exhibited notable body-weight loss. A 1-h LC50 of 991 ppm was calculated based upon these data. Gross examination revealed lung and liver congestion, and concentration-related alveolar irritation. Histopathological examination revealed concentration-related pulmonary edema and hemorrhage (observed only in hamsters exposed to the two highest concentrations).

In another inhalation test, dogs, monkeys, and rats were exposed to 1 ppm MMH for 24 h [676]. No adverse effects were observed during the exposure, in the clinical tests obtained biweekly during the post-exposure observation period, or in histopathological examination of animals sacrificed 30 day following exposure.

#### **11.1.2 Long-Term (Chronic) Inhalation Toxicity of MMH**

The animal pathology resulting from intermittent medium-term exposure to MMH vapors, using mice, rats, dogs, and monkeys, showed various types of organ damage [677]. The exposure pattern was 6 h/days, 5 days/week. Groups of 4 female monkeys, 8 female dogs, 10 male rats, and 10 male mice were exposed to 0 (control), 2, and 5 ppm for 6 weeks. The optical microscopic examination of microsections of tissues from monkeys and rats showed no experimentally induced lesions. Mice livers at the 5-ppm exposure level showed centrilobular cholestasis, bile duct proliferation, and centrilobular hemosiderosis. Kidneys and spleens also showed hemosiderosis. Bile duct proliferation could be seen in mice at 2 ppm, but one could notice the difference between animals exposed to 2 or 5 ppm. No such effect could be observed in dogs. In a second test series, the same number of fresh animals was exposed to 0 (control), 0.2 ppm continuously, and 1 ppm intermittently for 6 months, except that no monkeys were in the 1-ppm intermittent exposure test. No changes were seen in monkeys, dogs, or rats. Mice suffered hepatic splenic and renal tubular hemosiderosis, which was most pronounced in the group that was exposed continuously for 2 months.

Mice, rats, dogs, and monkeys exposed to 0.2-ppm MMH continuously for 6 months. showed toxic symptoms and hemolytic changes comparable with those observed in the intermittent exposure to 1 ppm MMH [676]. These two exposure

conditions were approximately equivalent in terms of total weekly dose ( $C \times T$  product). Rat growth rate was depressed during a 0.1-ppm/90-day inhalation test. Beagle dogs showed significant increases in serum phosphorus and alkaline phosphatase. Significant hemolytic effects of MMH were obvious from blood analysis of hematocrit, hemoglobin, RBCs, white blood cells, and reticulocytes in dogs and monkeys during and after the exposure and comparing with results before exposure or simultaneously kept controls. Some animals also showed gross pathological changes as livers with a nutmeg appearance. No adverse effects were seen in animals exposed to 0.04 ppm.

Dogs, monkeys, rats, and mice exposed to 2 and 5 ppm MMH intermittently for 6 months, all showed distinct hepatic damage [673, 674, 678]. Some of the mice died during the exposure, but only at the two highest concentrations.

Extending these tests (but not concurrent tests!) to lower concentrations, groups of 8 dogs, 4 rhesus monkeys, 50 Wistar rats, and 40 ICR mice were exposed for 6 months to 0.2, 1, 2, and 5 ppm MMH intermittently for 6 h/day, 5 days/week [679]. Another group was exposed to 0.2 ppm continuously for 6 months. The major chronic effects observed were caused by the affinity of MMH to RBCs. The effects were greatest in dogs, but also noticeable in monkeys. All exposed animals were sacrificed and necropsied immediately at the end of the 6-month exposure period. Results of these experiments have shown that MMH produced a dose-related hemolytic anemia with Heinz body formation for which there appears to be no threshold effect level. Anemia was reversible upon removal of animals from further exposure. Without a post-exposure observation period, it was possible that some latent effects of MMH exposure were overlooked. Dose-dependent changes in the myeloid/erythroid elements of bone marrow were also observed.

Four animal species were exposed for 1 year to selected vapor concentrations of MMH to determine its long-term toxic and oncogenic effects [680]. Year-long exposures of animals to MMH were conducted at a wide range of concentrations: 0.02, 0.2, 2.0, 5.0 ppm (rats); 0.02, 0.2, 2.0 ppm (mice); 0.2, 2.0, 5.0 ppm (hamsters); and 0.2, 2.0 ppm (dogs). Rats, mice, and hamsters were held for 1 year post-exposure whereas dogs were held for 5 years post-exposure. Exposed hamsters showed pathological changes characteristic of chronic irritation of the respiratory tract. Submucosal cysts, rhinitis, and epithelial hyperplasia increased in incidence in the exposed hamsters. Nasal tumors were present in hamsters exposed to the two higher concentrations. There were significant increases in irritation of the nasal cavity such as nasal inflammation, plasmacytosis, and hemorrhage in the mandibular lymph nodes of exposed mice. Adenomas and adenomatous polyps were seen in the nasal mucosa of a few mice exposed to 2.0 ppm MMH. There were significant increases in primary lung and liver tumors in the mice exposed to 2.0 ppm. No neoplastic changes were found in either the rats or the dogs.

## 11.2 Oral and Injection Toxicity of MMH

A large number of studies were performed where MMH was introduced into the body of test animals other than by inhalation or skin absorption. MMH was administered by intratracheal intubation, intravenous injection, intraperitoneal injection, subcutaneous injection, or orally with or without use of a stomach tube. The acute toxicity of MMH when introduced into the body through pathways other than inhalation is summarized in Table 47. In all cases listed in these tables hydrazine was more toxic than any of the methylhydrazines. This comparison is based on a weight basis (mg administered/kg body weight of animal). Under ordinary conditions of hydrazine usage, the

**Table 47:** Acute toxicity of methylhydrazine based on oral, topical, or injection administration methods.

| Dose, mg/kg                                                        | Mode of administration | Test animal | Symptoms observed                | Mortality ratio | References |

Additional toxicity data sources: [686, 687]

prime concern should be respiratory toxicity, on which basis hydrazine is less hazardous because of its lower volatility. The experiments summarized in Table 47 may not all have administered free methylhydrazines in solution. In many instances, the free bases were neutralized to pH 7 and dissolved in isotonic saline, in particular for intraperitoneal or intravenous administration.

Technicians servicing post-flight NTO/MMH thrusters and not wearing protection might be exposed to MMHN, a solid and hygroscopic substance. This is why MMHN was included in Table 47.

Prior to 1963, little was known about the mechanism of toxic action of hydrazine(s). The possibility of interference with  $\gamma$ -aminobutyric acid formation and vitamin B<sub>6</sub>-dependent enzymes was just beginning to emerge. A better understanding of the mechanism has been gained only during the past 50 years. Descriptions of the symptoms of acute poisoning of rats by hydrazines suggested that hydrazine N<sub>2</sub>H<sub>4</sub> itself acts in a way that is different from MMH or UDMH.

Table 48 is a juxtaposition of acute toxicities of hydrazine in comparison with MMH and UDMH. Based on these data, MMH is the most poisonous with the lowest LC50 and LD50 of the three rocket fuels tested.

**Table 48:** Comparison of acute toxicity of hydrazine, methylhydrazine, and unsymmetrical dimethylhydrazine (sorted by mode of administration).

| Test animal                                             | Mode of administration | N <sub>2</sub> H <sub>4</sub> | MMH | UDMH | References |

Three groups of hamsters and drinking solutions were used to investigate the carcinogenic effect of MMH in drinking water: **(1)** Control—drinking water adjusted to pH 3.5 with HCl; **(2)** buffered MMH solution—0.01% MMH in drinking water adjusted to pH 3.5 with HCl; **(3)** unbuffered MMH solution—0.01% MMH in drinking water not pH ad-

justed [690]. Each of the groups receiving MMH consisted of 30 hamsters. There were 17 controls. At the beginning of the study, the hamsters were approximately 5 months old. A 0.01% MMH/tap water solution stored in feeder bottles suffered a loss of approximately 60% of the MMH content over a 24-h period. If the tap water was chlorinated, that alone would destroy much of the MMH. The pH of the MMH/water solution had a great effect on rate of decomposition. To determine hemolytic effects of MMH, hematocrit and RBC measurements were made on blood samples taken by orbital puncture from 5 hamsters in each experimental group at 7, 11, and 15 months. Depressed hematology values, evidence from RBC destruction was clearly demonstrated for both groups of MMH-dosed animals. The overall tumor incidence for group I (MMH + tap water) was 16%, group II (MMH + pH 3.5 water) was 24%, and group III (control) was 31% (!). These findings are in contrast to the findings of Toth and Shimizu [691]. They reported a 54% incidence of Kupffer cell sarcomas, a 14% incidence of cecal tumors, and an overall tumor incidence of 101% in 50 male hamsters. Ninety-nine control animals had an overall tumor rate of 27% (!) with no Kupffer cell sarcomas and 1 cecal tumor reported. The dosage of MMH in the Toth and Shimizu study was 0.01% administered in drinking water for the lifetime of the animals. The small numbers of animals involved in both laboratory studies plus the absence of a high incidence of neoplasia in the MacEwen and Vernot experimental groups precludes valid conclusions on the oncogenicity of MMH administered at 0.01% in water *ad lib* for life to hamsters, and the results were in essence negative.

### 11.3 Blood Effects of MMH

In the reaction between MMH and blood, a concurrent effect of some physiological importance following exposure is the oxidation of hemoglobin to methemoglobin. There are species differences in the level of hemoglobin oxidation under the influence of MMH. The necessity for the presence of oxygen during the reaction was demonstrated, and during the course of the reaction some nitrogen and methane were liberated. Measurable methemoglobin occurred over a relatively narrow range of MMH concentration [692]. Denaturation of the globulin and precipitate formation occurred when MMH was in excess, possibly because of the reaction with sulfhydryl groups of the protein. As the aerobic MMH/hemoglobin reaction *in vitro* proceeded, the mixture turned from bright red to purple brown in appearance, during which an observable release of gas occurred.

The effects of MMH on human RBCs were studied *in vitro* [693, 694]. These effects are characteristic of oxidant damage and included methemoglobin formation, Heinz body production, and a decreased level of reduced glutathione. Cell morphology was examined by light microscopy and the cells showed a distorted appearance with a loss of the biconcave shape after 2-h exposure. There was no change in cell osmotic fragility. MMH did not exhibit any effect on various protective enzyme sys-

tems involved in maintaining the redox equilibrium in the cell. It appeared that the hemolytic effect of MMH observed *in vivo* was caused either by a direct action of this oxidant on cell membrane (which was not obvious on fixed morphological observation) or by the effect of Heinz bodies on cellular integrity leading to a decreased cellular 'deformability' and premature removal of the injured cells from the circulation by the spleen, or both.

The direct effect of MMH on the cytoplasm of red cells is manifested by Heinz body formation. *In vitro* MMH/blood reactions were examined to study the effects of MMH on human RBCs [695]. Glutathione (GSH) levels, methemoglobin, and Heinz body production were measured. Biological reduction in the red cell was maintained by GSH and various reductases, which required either NADH from the Embden–Meyerhof pathway or NADPH from the hexose monophosphate shunt (HMP) pathway. The activities of glutathione reductase (GSSG-R) and two enzymes in the HMP pathway, glucose-6-phosphate dehydrogenase and 6-phosphogluconic dehydrogenase, were determined as a decrease in HMP enzyme activity could partially explain the striking susceptibility of mammalian RBCs to MMH exposure and a decrease in GSSG-R could explain the decrease in GSH. Osmotic fragilities of red cells were examined as a measure of red cell membrane integrity. The development of Heinz bodies was followed by light microscopy and freeze-cleave electron microscopy, and an attempt was made to correlate morphological alterations in red cells exposed to MMH with biochemical and functional changes. Methylhydrazine concentration in the blood can be correlated with the received dose by using a nomogram [696, 697].

Hemolysis is the breaking up of red blood corpuscles (erythrocytes), rendering them ineffective for the transport of oxygen. Blood cell destruction and anemia are less frequently observed after inhalation or subcutaneous injection, but only in severe cases of chronic poisoning.

Methylhydrazine was injected into rats, rabbits, and guinea pigs, and subsequent levels of methemoglobin in the blood were measured [698]. Peak levels of methemoglobin occurred within an hour, but were less than 5% of blood hemoglobin, with doses of MMH up to 0.54 mmol/kg. In contrast, 5- to 8-fold higher levels have been previously observed in anesthetized dogs treated with comparable doses of MMH. *In vitro* incubations of MMH with blood from rats, rabbits, guinea pigs, dogs, and human subjects produced peak levels of methemoglobin within an hour. Peak levels were 4- to 8-fold higher when human or canine blood was incubated with MMH than when rat, rabbit, or guinea pig blood was similarly incubated. These results demonstrated that there is a marked difference among species in the levels of methemoglobin found either *in vivo* after MMH injection or *in vitro* during incubation of blood with MMH.

During an *in vitro* study of the MMH effect on blood, the aerobic MMH–hemoglobin reaction caused the appearance of the mixture to change from bright red to purple brown in appearance, during which an observable release of gas occurred [692]. With high MMH to heme ratios, more than 2:1 on a molar basis, rapid denaturation and precipitation followed. At lower ratios the rate of hemoglobin con-

version was directly proportional to the MMH level. Identification of the compound formed as methemoglobin was based on spectral analysis of the compound itself and comparison with published spectra. In unlimited aerobic reactions of MMH with dog blood, both the rate of methemoglobin formation and the total reached were directly proportional to the original concentration of MMH.

The hemolytic action among all the alkyl hydrazines is most pronounced with MMH [672]. Excessive MMH exposure can readily be recognized by methemoglobinemia [699]. Anemia caused by MMH is characterized by methemoglobinemia, a decreased level of reduced glutathione, and Heinz body formation. Human red cells were exposed *in vitro* to three levels of MMH for 2, 4, or 6 h. Glucose utilization, lactate production, and ATP levels were measured to determine effects on glucose metabolism. Osmotic fragilities, red cell potassium concentration, and malonyldialdehyde levels were measured to assess membrane effects [694]. This effect is species dependent [698]. However, when comparing the erythrocyte damage in freeze-etched specimens by MMH and phenylhydrazine, extremely high doses of MMH were required to produce the same effect as that caused by phenylhydrazine at low concentrations [700].

As opposed to MMH, hydrazine and UDMH cause hematological changes in rabbits or mice only at very high concentrations [701]. At high concentrations, hematological changes are frequently overshadowed by other symptoms of acute poisoning.

In the group of three hydrazines tested (hydrazine, MMH, and UDMH), MMH was the most effective agent at producing hemolytic anemia in test animals [702]. Effects of MMH, such as methemoglobinemia and Heinz body formation, were observed at MMH concentrations 8–10 times lower than the concentration at which the first effects were observed for hydrazine itself. In contrast, UDMH did not cause methemoglobinemia or Heinz body formation.

The amount of methemoglobin formed is a sensitive indicator that can be correlated with the MMH dose received, as shown not only in animal tests with anesthetized dogs, but also with human blood *in vitro*. Because the methemoglobin content of blood from an accident victim can be rapidly determined, it has been proposed to use the methemoglobin concentration as an index for the severity of exposure [703]. Of course, this index is reliable only if no other toxic agents that also cause methemoglobinemia (e.g., NO<sub>2</sub>) are involved.

Methylhydrazine may disturb the blood clotting mechanism. The *in vivo* effects of MMH on the coagulation mechanism, in particular the prothrombin activating mechanism and the fibrinolytic mechanism, was studied in rats anesthetized with ether [704]. The MMH concentration chosen was 60% of the LD<sub>50</sub> determined in separate experiments. No significant changes were found in the prothrombin time or partial thromboplastin time, but the thromboplastin generation time was increased, and total profibrinolysin was decreased significantly.

### 11.4 Central Nervous System Effects of MMH

Similar to the mechanism for hydrazine, a likely mechanism for MMH-induced seizures is the formation of the methylhydrazone of pyridoxal phosphate, a reaction that takes this coenzyme away from the synthesis of glutamic acid decarboxylase (GAD), an essential precursor of putative central neural inhibitory transmitter such as  $\gamma$ -aminobutyric acid.

Laser surface photobleaching, electron microscopy, and electrophysiological measurements on hydrazine- and MMH-treated vertebrate cell cultures demonstrated a marked effect of MMH on cell mitochondria and  $\text{Ca}^{2+}$  ion flux [705]. *In vitro* cells treated with  $\text{N}_2\text{H}_4$  or MMH showed changes in lateral surface mobility. Methylhydrazine and other hydrazines inhibit  $\gamma$ -aminobutyric acid (GABA) synthesis in the central nervous system (CNS), but others cause a several-fold increase of GABA levels in the brain [706].

Exposure to MMH can cause dose-related CNS disturbances ranging from tremors to tonic-clonic convulsions to death [707]. Diazepam (DZ) acts at the GABA receptor site, and it is also here that ivermectin (AVM) is pharmacologically active. Mice were injected with 30 mg/kg MMH. Groups of 12 mice each were then given varying doses of AVM (5, 10 or 15 mg/kg), or AVM + DZ combinations (5 mg/kg AVM with 5 mg/kg DZ, 10 mg/kg AVM with 5 mg/kg DZ). Times elapsed to first convulsion and time to death were recorded over the next 7 h and all groups were monitored over the next 7 days. Times to convulsion were not altered with AVM alone, but death was significantly prevented with AVM dosages. A combination treatment of 10 mg/kg AVM with 5 mg/kg DZ resulted in no seizures or deaths.

The latent effect of MMH on the tendency of cats to suffer seizures (stimulated by electrodes) lingers on for a long time after MMH administration [708, 709]. Using a statistical index of seizure susceptibility, it was shown that cats with prolonged seizure latencies also showed significantly higher post-discharge thresholds.

Lethal doses of 18 mg MMH/kg (intraperitoneally) and sublethal doses of 9 and 5 mg MMH/kg (intraperitoneally) were used to study lethal, convulsive and sub-convulsive symptoms in cats [710]. The onset latency of these symptoms was directly related to dose.

Cats were trained and tested in a special runway apparatus to provide a reliable indication of performance changes over a 6-h period following the administration of 1, 2 or 4 mg/kg MMH [685, 711]. These low doses significantly altered locomotor performance, both during drug session testing and saline control testing carried out 24 h later. Within 30 min after injection of all three doses of MMH, runway performance was depressed. At 2 and 4 mg/kg, this influence was profound and was associated with overt physiological symptoms of toxicity. A total disruption of performance occurred with 4-mg/kg doses when tested 2–5 h after administration. Performance was still depressed after 24 h following 4 mg/kg, but was actually facilitated at this same point following the lower 1- and 2-mg/kg doses. For these doses, a pre-convulsive syndrome

was described involving recurrent and sustained symptoms including vomiting, panting, salivation, hyperactivity, and subcortical seizure activity. The acute toxicity LD<sub>50</sub> value for MMH was established as 15 mg/kg, and the CD50 as 7 mg/kg. Doses of 18, 9, and 5 mg/kg were then studied systematically in an effort to classify lethal, convulsive, and sub-convulsive symptoms. Convulsions were specifically delayed or prevented in animals trained to suppress movement through the use of a special electroencephalogram (EEG) conditioning technique.

The effects of dorsal column lesions on electrocortical activity and susceptibility to MMH-induced seizures in cats were studied with 11 animals, prepared with indwelling cortical electrodes over hind-limb and fore-limb projection areas of somatosensory cortex, which received bilateral lesions of the dorsal columns at either high (C1–C3) or low (C5–T1) cervical levels [712]. After a 3-week postsurgical period, each animal was administered a convulsive dose of MMH. Seizure latency was measured from the time of MMH injection to the onset of tonic–clonic convulsions. Latency data were compared with those from intact animals ( $N=18$ ). Results indicated a progressive and significant increase in seizure latency with more encephalad dorsal column transection.

Methylhydrazine may have adverse effects on the CNS. In one of the first test series involving nine macaque monkeys, at the rate of one injection per day, two control injections of saline alternated with two MMH intraperitoneal injections (each containing 2.5 or 5 mg MMH/kg) [713, 714]. The two MMH injections were 48 h apart. No difference in performance could be observed as the result of any of the injections at either concentration level, but there was a greater incidence of clinical signs in the group receiving a higher dose. The few performance decrements observed would usually precede clinical signs of incipient poisoning. In a similar test, nine macaque monkeys were injected twice with either 2.5 or 5 mg MMH/kg [715]. Operant task performance was not affected by either dosage of MMH, but there was a greater incidence of clinical symptoms in those monkeys exposed to 5 mg/kg. In over half the cases, performance degraded prior to clinical symptoms becoming apparent, typically within 1–2 h after the first MMH poisoning. In 3/18 cases clinical symptoms did appear without a performance decrement, but in 4/18 cases a performance decrement occurred in the absence of clinical symptoms. When initial 2.5 or 5.0 mg/kg injections are given one might predict that performance decrements might occur between 1 and 2 h and clinical symptoms between 2 and 2.5 h in about half the subjects. A second exposure might be expected to produce performance decrements between 1 and 2 h and clinical symptoms between 2 and 3 h in the majority of subjects. If a subject is influenced by MMH, clinical symptoms will likely disappear between 3 and 9 h following injection, and performance should return to baseline level between 3 and 30 h.

Two other monkeys, whose behavior was maintained on an avoidance schedule that required continued discrimination of cues, were given 0.5–4 mg MMH/kg injections [716–719]. Exposure to these comparatively low doses resulted in significant behavioral stimulation. There seemed to be a cumulative effect of repeated exposure in intervals of 24 h.

### 11.5 Brain Effects of MMH

In advanced states of MMH poisoning, the victim suffers seizures and convulsions that seem to be triggered by blockage of essential brain centers. Significant effort has been devoted to studying this mechanism in test animals and finding possible preventive or curative agents.

The influence of hydrazine, MMH, and UDMH upon possible transmitter substances in rat brain was studied to determine the time elapsed between injection and onset of convulsions [720]. Mesencephalon-diencephalon, medulla, cortex, and cerebellum were separately examined. All the hydrazines increased 5-hydroxy-tryptamine, particularly in cortex, where a three-fold increase was found. All the hydrazines increased norepinephrine by small amounts (48% maximum), the effects being greatest in the cortex and least in the mesencephalon-diencephalon. MMH and UDMH lowered GABA by small amounts (17% maximum) in medulla, cortex, and the mesencephalon-diencephalon, but the effects on cerebellum were small or absent.

The toxic action of MMH or UDMH may be mediated by the inactivation of pyridoxal in the brain. One possibility considered was the formation of a hydrazone between the pyridoxals and the substituted hydrazine. Pyridoxal-dependent enzymes were investigated [721]. MMH inhibited both glutamic acid decarboxylase and DOPA decarboxylase. Transaminases that required AKGA as a substrate were not affected by the hydrazines tested. A mathematical model for hydrazines-induced convulsions was developed that can predict the time lapse after administration of the convulsigen and the onset of seizure if only three data points are given.

The brain effects and behavioral changes as the result of MMH intoxication were studied by electroencephalography in cats [710, 722]. The acute lethal toxicity value (LD50) for MMH was established at 15 mg/kg, and the convulsive toxicity value (CD50) at 7 m/kg. Doses of 18, 9, and 5 mg/kg were then studied systematically in an effort to classify lethal, convulsive, and sub-convulsive symptoms.

The cerebral neuroelectric evoked response in the unanesthetized cat showed that convulsive doses of MMH consistently produced a large increase in the primary negative response of the somatic sensory cortex, which progressively changed with time and approached peak levels starting approximately 1 h before seizure onset [723]. The response changes may be a useful index of impending seizure in a variety of toxic and clinical conditions.

It was shown that MMH disturbs the blood cerebrospinal fluid glucose flux, but catastrophic failure of the performance of brain and nerve cells embedded in that fluid is not caused by elevation of glucose levels observed following MMH administration in monkeys [724, 725]. The convulsions following intravenous administration of MMH to mice or rats are caused by direct action on the brain because they are abolished caudal to a cord transection or by treatment with *d*-tubocurarine [681]. Convulsions are also elicited in the anesthetized dog when MMH is injected into the cisterna magna.

Whereas doses of 1–9 mg/kg administered cisternally produced convulsions, doses in excess of this caused death within a few minutes. When data from mice convulsion,  $\log(\text{time to onset of convulsions})$  were plotted against  $\log(\text{dose})$ , a straight-line relationship was obtained. In mice, MMH-induced seizures can be prevented completely with secobarbital (50 mg/kg), phenobarbital (100 mg/kg), or Mesantoin (200 mg/kg). A survival rate of 90–100% has been achieved in mice by repeated administration of anti-convulsants for a period of 30 h following administration of an otherwise 100% fatal dose of 60 mg MMH/kg. So far, repeated attempts to extend the same treatment to dogs have failed. In an attempt to localize the site of convulsant action in dogs, the neuraxis was transected at various levels to find the lowest portion of the CNS that might initiate hydrazine-induced convulsions. Decorticated, decerebrated, and cervical cord-dissected animals responded differently. The results indicate that a small area in the midbrain is essential for the occurrence of convulsions in dogs poisoned by MMH or UDMH.

The influence of sub-convulsive exposure to MMH on sleep-waking patterns and upon thalamocortical conduction was measured by polygraphic recordings classifying states of sleep and wakefulness over a 10-h period following either saline or MMH (5 mg/kg, intraperitoneal) injections [726]. MMH at this dose caused no overt behavioral disruption on transient observation; however, analysis of polygraphic data disclosed a significant depression of sleep and disruption of normal diurnal rhythms. Sleep suppression lasted approximately 6 h and was followed by a profound sleep rebound. The influence upon sleep could have equally serious and different consequences in performance.

A lumped parameter mathematical model including extracellular fluid, intracellular fluid, and cerebrospinal fluid compartments has been applied to describe MMH distribution kinetics in the blood and cerebrospinal fluid of Rhesus monkeys [727, 728]. Ten monkeys with an average weight of 5.5 kg, were given intravenous infusions of MMH whereas blood and cerebrospinal fluid samples were periodically collected and analyzed for MMH. The mathematical model was used to simulate the infusions and the simulations were compared with experimental data to validate the model and to evaluate the mass transfer parameters required by the model.

Toxic and convulsive responses to MMH were compared in two groups of rhesus monkeys [729]. One group received 12 weeks of feedback training with reinforcement provided for the production of rhythmic central cortical 12–14 Hz EEG activity (the sensorimotor rhythm or SMR) in the absence of movement and concurrent 8–11 Hz EEG activity. A second group was also studied but without feedback training. Three of the four trained animals demonstrated reliable acquisition of the rewarded response. Following training, a convulsive dose of MMH was administered to both groups. Trained animals showed a significantly prolonged latency to generalized seizures, fewer overall seizures, and a greater incidence of sustained quiescent behavior. Toxic responses of the two groups, including emesis and episodes of agitated behavior, were comparable. These findings indicate that the threshold for MMH-induced seizures can be

modified in primates through EEG feedback training, as shown previously in the cat. A specific change in central motor control mechanisms was proposed as an explanation for this effect.

### 11.6 Cardiac Effects of MMH

The cardiovascular effects of hydrazines may be related to changes in norepinephrine and histamine levels in the heart muscle. Studies of the effect of hydrazine, MMH, and UDMH injections on blood pressure and heart rate in the conscious or anesthetized dog showed that the effects caused by the four hydrazines were quite different [682]. The cardiac slowing induced by MMH or hydrazine has been ascribed to medullary (vagal) stimulation because changes in rate were not observed after nerve blocking with hexamethonium injections.

Methylhydrazine (0.31 mmol/kg) or hydrazine (0.31 mmol/kg) produced significant elevations of norepinephrine in the heart of rats [730]. The increase caused by MMH can be explained by the fact that it is also a potent monoamine oxidase (MAO) inhibitor, but the effect of hydrazine is more difficult to explain. MMH also acts as a diamine oxidase inhibitor. In a group of several hydrazine derivatives tested, MMH was the only one that also increased histamine levels in the heart.

### 11.7 Dermal (Cutaneous) Toxicity of MMH

Most hydrazines, including MMH, are water soluble and can permeate the skin barrier. They also often form chemical bonds to carbonyl and acid groups in the skin material. In one series of tests, when applied directly to the skin of rabbits, hydrazine caused corrosive skin disintegration, whereas MMH caused a mild edema, which disappeared after 24 h, leaving a bleached appearance at the site of application [501].

In skin absorption tests with MMH on dogs with doses up to 270 mg/kg, no permanent effects were observed as the result of a single application [731, 732]. Water washing and tannic acid solution soaking were evaluated as first aid treatments to arrest MMH absorption through the skin [733]. The blood plasma MMH concentration and the progressed state of methemoglobinemia as it is commonly observed during the first 2 h after application of MMH to the chests of dogs can be expressed as a function of body weight and dose [696, 697]. Calculations are made easy by use of a nomogram, which may allow one to extrapolate to other body weights and (with some precautions) other species. In the absence of dose–response data from humans, these graphs are for the time being the best source for prediction of the effects of accidental MMH spills on the skin of propellant-handling personnel.

Methylhydrazinium nitrate is never produced in bulk as an industrial commodity (unlike methylammonium nitrate). It may form inadvertently during the shutdown of

bipropellant thrusters from the dribble volume of oxidizer and MMH slowly reacting after combustion has ceased. Technicians or astronauts who are servicing post-flight NTO/MMH thrusters without protecting themselves with gloves may accidentally absorb MMHN through the skin. Tests with rats and hamsters have shown that MMHN is readily absorbed through the skin and that the topical LD50 of MMHN is similar to that of MMH (when compared on a molar basis) [501, 502] (see Table 47).

A study of the toxicokinetics of MMH percutaneous absorption in rabbits was based on two kinetic models and compared with test results where MMH 10 mg/kg was administered intravenously in rabbits in one test and MMH 25 or 6 mg/kg was administered percutaneously [734]. The toxicokinetic characteristics of MMH in rabbits showed that MMH can be absorbed rapidly and the rate of diffusion crossing skin would be very fast. The speed of distribution through the body was much faster. MMH was distributed throughout the body and accumulated in peripheral compartments. The elimination of MMH was quite rapid.

### 11.8 Eye Effects (Ocular Toxicity) of MMH

Ocular toxicity studies of hydrazine and methylhydrazines showed that hydrazine caused permanent corneal damage, whereas methylhydrazines showed transient effects for only 2–7 days [504]. A study of the effect of MMH on frog cornea showed that even though MMH is a weaker base than hydrazine, the transparency of the cornea suffered more rapidly [735].

Animal test results showed that MMH easily passes through the blood/aqueous humor barrier to enter the aqueous humor bathing the endothelial layer of the cornea. Dog corneas became edematous within 5–6 h after MMH has entered the anterior chamber. The MMH concentration in the aqueous humor was ~75% of that in the blood. In clamped cornea tested *in vitro*, marked swelling occurred within 15–20 min after exposure to MMH at concentrations of  $10^{-2}$  to  $10^{-4}$  M. Lower MMH concentrations ( $10^{-5}$  to  $10^{-7}$  M) caused the same amount of swelling, only after a longer lag time. The rate of swelling was reduced soon after the MMH was removed.

Methylhydrazine caused hydration of the endothelium, with subsequent swelling of the cornea. Pharmacological doses of arginine inhibited the swelling effect of MMH [736].

### 11.9 Therapy and Prophylaxis of MMH Poisoning: Treatment of Accidental Poisonings with MMH

Propellant handling personnel should undergo routine periodical health examinations and their medical records need to be reviewed for slow changes in body functions. Considerable information that is useful in evaluating the adequacy of

control measures can be obtained by compiling and analyzing clinical laboratory results, physical findings and subjective complaints.

Although there are recommendations on the treatment of accidental poisonings with hydrazine  $N_2H_4$  or UDMH, no such specific recommendations could be found for cases of MMH poisoning. Eighteen different compounds were tested for their therapeutic effect against hydrazine, MMH, or UDMH poisoning (intraperitoneal, mice) [682]. Of those found to be effective, arginine and ornithine provided clear-cut protection from death and convulsion caused by otherwise fatal hydrazine doses, but the two amino acids were ineffective against MMH or UDMH. Amino-oxyacetic acid or pyridoxine provided effective protection against MMH or UDMH poisoning but were ineffective against hydrazine.

Although a significant number of experimental studies were performed in the late 1950s through the mid-1960s, conflicting information exists concerning the most appropriate treatment for accidental exposures of humans to hydrazines. A cross-sectional study evaluating the most commonly suggested therapies against poisonings by the most common rocket fuels such as hydrazine, UDMH, MMH, and Aerozine-50, therapies such as pyridoxine, traditional anti-seizure therapies, or arginine is needed to clarify the treatment implications for human exposure [737]. Treatments that have been useful for hyperammonemic states, such as those for urea cycle defects, have significant potential for the improvement of treatment for hydrazine(s) accidental exposure.

Anyone reading about the results of various experimental animal studies dealing with prophylaxis and therapy of hydrazine poisoning using pyridoxine = vitamin  $B_6$  may still have some doubts as to whether this chemical would help in human accident situations. The protective efficiency of pyridoxine and other forms of vitamin  $B_6$  has been disputed and questioned. There are summaries of hydrazine or UDMH accidents and several accounts of the successful application of pyridoxine therapy to victims of hydrazine or UDMH poisonings, but it is not known if the same therapy would help in cases of poisonings by MMH.

Dogs treated with single intraperitoneal injections of up to 30 mg MMH/kg as part of a renal toxicity study were successfully protected from the acute convulsigenic effects by co-administration of 100–200 mg pyridoxine/kg. In a group of 11 dogs treated with 10 mg MMH/kg, 7 were protected with 100–200 mg pyridoxine/kg. Most of the unprotected dogs died within a few hours, whereas protected animals lived to the scheduled necropsy after 1 day. In a group of 12 dogs exposed to 15 mg MMH/kg, all animals could be protected by 200 mg pyridoxine/kg. Similar results were obtained at 20 and 30 mg/kg.

Large doses of pyridoxine reduced the convulsant effect of MMH in cats [708, 709]. The convulsive, toxic, and lethal effects of a single subcutaneous injection of MMH given to Swiss mice were successfully prevented by administering pyridoxine hydrochloride before and/or after injection [738]. Exposure to MMH can produce convulsions and death, probably because of the inhibitory effect of MMH on GABA synthesis.

A widely recommended prophylactic and therapeutic agent is pyridoxine, but because of the large amounts required, and the low solubility of pyridoxine, the injection volumes required for effective treatment can result in severe tissue irritation and trauma. The therapeutic effects of muscimol, DZ, and pyridoxine, and certain combinations of these compounds, against MMH-induced convulsions and lethality were tested by injecting mice with convulsive and lethal doses of MMH, and with varying doses of the three antidotes or combinations of them, and recording the incidence of convulsions and death, and the times needed to achieve an effect [739]. All drugs had a protective effect, but combinations containing DZ and either pyridoxine or muscimol were the most effective antagonists to MMH convulsions and death. The dose–response curves were shifted to the right, and the times to convulsion and to death were significantly prolonged. One group of mice (10 male and 10 female) were given 40 mg MMH/kg, and a mortality rate of 80–100% was observed. The same dose together with two injections of 200 mg pyridoxine hydrochloride/kg each at 1-h intervals did not cause any fatalities in either of another two groups of 10 mice. Combinations of DZ and pyridoxine were the most effective antagonists against MMH-induced convulsions and death. These types of tests were later extended to rhesus monkeys, also with monitoring of brain function in EEGs [729, 740, 741]. Three groups of monkeys were exposed to either MMH alone or MMH with simultaneous pyridoxine administration. Animals receiving MMH alone displayed emesis, preictal responses, and generalized seizures within the first 75 min after MMH injection. MMH/pyridoxine-treated animals showed some emesis but no preictal or ictal behavior during this period. MMH/pyridoxine-treated animals that were also restrained in a primate restraint chair did not show these symptoms. Immobilization reduced the susceptibility to hydrazine-induced seizures. Pyridoxine does not appear to be as effective against MMH poisoning as it appeared to be against UDMH poisoning. Based on tests in male ICR mice, combinations of pyridoxine and DZ or muscimol were more effective than pyridoxine alone [742].

The behavior-changing effect of MMH on the learned behavior of monkeys can be mitigated if pyridoxine is administered intramuscularly simultaneously with MMH intraperitoneally [718]. Ten macaque monkeys were trained on a complex behavioral program containing both aversively avoided and appetitively rewarded tasks. One group was given MMH only, and the other group was given MMH with the prophylactic antidote of pyridoxine. The second group was able to continue to perform tasks in which the first group failed.

The pyridoxal hydrazones of the various hydrazines form as intermediates during metabolism of hydrazines, surprisingly with an exceptionally high toxicity of their own [743]. A comparative study was made of the toxicity and convulsion activity of MMH, UDMH, and their pyridoxal and pyridoxal-5-phosphate hydrazones. The hydrazones of UDMH were more toxic than UDMH itself. In the case of MMH, the convulsion times of hydrazones and free MMH were about equal; but death appeared earlier with the hydrazones. This work implies that pyridoxal exacerbates rather than alleviates the convulsant activity of UDMH and MMH, and thus should not be considered an

antidote. It was discovered that the pyridoxal hydrazone of UDMH is more toxic than UDMH, which is truly remarkable. With MMH and its hydrazone, the convulsion times are equal, but death occurred earlier with the hydrazone.

In rhesus monkeys that were restrained in a chair, the convulsant effect of 15 mg MMH/kg could be avoided by anti-convulsant drugs, pyridoxine, and DZ [740, 741]. Valproic acid or carbamazepine were not effective.

The influence of arm restraint and pyridoxine respectively on preventing seizures in MMH-poisoned monkeys was investigated [744]. Control animals with no protective prophylactic treatment displayed emesis, pre-ictal responses and generalized seizures within the first 75 min. post-MMH-injection. Pyridoxine-treated animals showed emesis but no pre-ictal or ictal behavior during this period, whereas arm-restrained animals showed no emesis, pre-ictal or ictal behavior. Control animals exhibited at least three generalized seizures, after which chemotherapy was administered within the first 100 min. post-MMH-injection. Neither pyridoxine-treated nor arm-restraint animals showed any generalized seizures during a standard 240-min. observation period, although both groups eventually displayed emesis and pre-ictal responses. The protective effects of pyridoxine were interpreted within the context of established neurochemical influences of the hydrazines on the synthesis of the inhibitory neurotransmitter GABA.

## 11.10 Effects of MMH on Metabolism

The effects of MMH on metabolism, the immune system, enzymes in the brain, liver, and the blood were already summarized in a chapter of the hydrazine book [745].

### 11.10.1 Metabolic Fate of MMH

Besides observing adverse effects of MMH on various parts of the body, it is also of interest to determine which pathways MMH follows through the body and what fraction is excreted unchanged or as an intermediate additive with other metabolites or totally metabolized to nitrogen and water [746]. MMH resembles ammonia in being more rapidly excreted in acidic urine. Metabolic changes (not just digestion) suffered by hydrazines as they pass through the body are called “biotransformation.” In addition, toxicokinetic studies look at the rate at which the poison is distributed throughout the body and at what rate it disappears through either metabolism or clearance in the unadulterated state. Many of the early studies of metabolic pathways were done by identifying agents that could block a vital step of a metabolic cycle, then observing which metabolic substrates accumulate when the blocking agents are administered to living animals. Additional information is available in the hydrazine book [745].

### 11.10.2 Kidney Function (Nephrotoxic) Effects of MMH

In kidney function studies with dogs, the effects of hydrazine, MMH, or UDMH on *p*-aminohippurate (PAH) clearance were studied experimentally [747]. Dogs received 0.63 mMol hydrazine/kg, 0.63 mMol MMH/kg, or 0.5 mMol UDMH/kg intravenously. The animals were anesthetized during the experiment, and PAH and inulin were administered along with an intravenous infusion of dextrose. Dogs exposed to hydrazine had significantly decreased PAH and inulin clearance rates and decreased renal plasma flow (RPF) rates during the first 4 h after hydrazine injection. The decreased glomerular filtration rate (GFR) was attributed to decreased RPF. The decreased PAH clearance was most likely caused by decreased GFR and impedance in active transport by the proximal tubular epithelium. Animals also developed hemoglobinemia and hemoglobinuria. Dogs exposed to MMH had decreased PAH and inulin clearance rates. Within minutes after MMH administration, methemoglobin began to appear in the blood, and it appeared in the urine within 1 h. Intraperitoneal injections of 25–60 mg/kg MMH caused proximal tubule damage in kidneys of rats [748].

A new effect (not previously observed) as the result of chronic exposure of dogs to MMH was the severe renal damage. Histopathological examination of the kidneys revealed proteinaceous precipitates in the proximal tubules [749]. Monkeys exposed to MMH showed no change in renal function [676, 750]. Four groups of monkeys were given different MMH doses intraperitoneally as follows: (1) 7.5 mg/kg single injection; (2) 2.5 mg/kg daily for 14 day; (3) 5 mg/kg every other day for 14 day; and (4) 5 mg/kg daily for 5–10 days. A fifth group was kept as a control group and received saline injections only. The GFR was determined by endogenous creatinine clearance. RPF was determined by infusion of sodium PAH. Kidney tissue samples were taken by needle biopsy. There was no statistically significant change in renal function in any of the animals. However, examination of kidney biopsy samples under SEM revealed major changes in the subcellular morphology in all groups of monkeys as a result of MMH exposure. Changes were observed in both proximal and distal tubule cells. Changes were most pronounced in the animals from group 2 (as defined earlier in this paragraph). The nephrotoxic effects of exposure to MMH are much more severe in dogs than in monkeys. The animals exposed to 0.2 ppm MMH continuously for 6 months showed toxic alterations and hemolytic changes comparable with those observed in the animals with intermittent exposure to 1.0 ppm MMH. These two exposure conditions were approximately equivalent in terms of total weekly dose in parts per million  $\times$  hours.

In cases of acute MMH poisoning of dogs, most of the MMH was excreted through the kidneys and could be detected in the urine, although part of it may have been temporarily tied up with carbonyl compounds (sugars) from which it was released on hydrolysis [749, 751]. Unlike other hydrazines, MMH given to dogs produced RBC damage, leading to hemoglobinemia, hemoglobinuria, and severe hemoglobinuric nephropathy. This expressed itself by the appearance of hemoglobin in the tubules and the development of absorption droplets in the lining epithelial cells. If a large

dose of MMH was given, the epithelium later took on a different appearance, with the formation of giant cells or syncytial masses around the hemoglobin aggregates. The renal lesion was reversible if complications were avoided, and the only late effect was marked hemosiderosis of the kidneys, liver, spleen, and lymph nodes. Detailed histopathology was conducted on kidneys removed from dogs exposed to single intraperitoneal doses of 5–30 mg MMH/kg, and sacrificed after 8 h, 12 h, 2 days, or 8 days [752–754]. The animals receiving more than 10 mg/kg were protected against convulsions by administration of 100 to 200 mg/kg of pyridoxine hydrochloride. MMH excretion was similar to that of hydrazine, its parent base, except that MMH possessed a lower reabsorption rate.

### 11.10.3 Liver Toxicity (Hepatotoxic) Effects of MMH

Isolated hepatocytes and liver microsomes incubated with MMH, UDMH, or SDMH produced free radical intermediates that were detected by ESR spectroscopy by using 4-pyridyl-1-oxide-*t*-butyl nitron (4-POBN) as a spin trapping agent [755]. The spectral features of the spin adducts derived from all three hydrazine derivatives corresponded to the values reported for the methyl free radical adduct of 4-POBN. In the microsomal preparations, inhibitors of the mixed function oxidase system and the destruction of cytochrome P450 by pretreating the rats with  $\text{CoCl}_2$  decreased the free radical formation. Methimazole, an inhibitor of the flavin adenine dinucleotide-containing mono-oxygenase system, similarly decreased the activation of UDMH, but not that of MMH or SDMH. The addition to liver microsomes of physiological concentrations of GSH lowered by approx. 80% the intensities of the ESR signals. Consistently, incubation of isolated hepatocytes with methylhydrazines decreased the intracellular GSH content, suggesting that GSH can effectively scavenge the methyl free radicals. The results suggested that methyl free radicals could be the alkylating species responsible for the toxic and/or carcinogenic effect of methylhydrazines. It was theorized that CoQ10 scavenges free radicals generated from MMH or its metabolites. Other enzymes involved include cytochrome oxidase and MAO inhibitors and cytochrome P450 as an activator [756]. Cytochrome P450 is a heme-containing protein that takes part in many reactions of xenobiotics during biotransformation processes [757]. Of particular interest are reactions involving free radicals during oxidative metabolism of hydrazine derivatives, as some of these may lead to cancer. The metabolism of alkylhydrazines via oxidation by cytochrome P450 systems may involve carbon-centered free radicals.

Single toxic doses of MMH caused little morphological change in the liver [758]. No effects on hepatic protein synthesis by SDMH or MMH were observed. Liver mitochondria exhibited distinct changes as a result of fatty liver degeneration caused by hydrazine poisoning. Similar effects may be caused by MMH [705, 759]. Even naturally occurring MMH-containing glycosides such as gyromitrin can cause adverse effects on the lipids of rat liver [77, 78].

### 11.11 Carcinogenic Effects (Carcinogenicity) of MMH

A book on *Hydrazines and Cancer* was published in 2000 by Toth [760]. It is a very thorough review of carcinogenicity and includes test data with both natural and man-made chemicals, including MMH and UDMH. The same topic was discussed from a slightly different point of view, but in much more detail in Sections 4.4.3.8 and 4.4.3.9 of our 2001 book on hydrazines [745], including chapters on carcinogenicity, teratogenicity, and mutagenicity.

Several hydrazines have been shown to be carcinogenic in animal tests. As part of the overall effort to understand the conditions leading to development of cancer, and in order to find a cure of this highly complex disease, carcinogenic actions of hydrazines have been thoroughly studied. The carcinogenic action is most pronounced with SDMH and UDMH, not MMH.

### 11.12 Bacteriostatic Activity of MMH

Any toxic chemical spilled into the sewer system that finds its way into the sewage treatment plant bioreactors may do serious harm to the live bacteria that are performing the dirty job of cleaning up the sewage water so that it can be released into surface waters. As it turns out, depending on the concentration of the alkylhydrazine, some bacteria not only are not harmed, but actually thrive on it, in particular after part of the population has undergone mutations to become more hydrazine resistant.

The toxicities of hydrazine, MMH, and UDMH were determined for mixed and uni-cultures of nitrifying bacteria, denitrifying bacteria, and anaerobic methanogenic bacteria [761–763]. MMH was more toxic than hydrazine, which was more toxic than dimethyl hydrazine. The toxicity level numbers were small enough to preclude biological waste treatment of these compounds. Hydrazine was co-metabolized to nitrogen gas by *Nitrosomonas*.

During a series of experiments on the death rate kinetics of hydrazine-exposed cultures, it was noted that bacteria continued to grow in nutrient-free media, which suggested metabolites derived from lysed cells might have been metabolized. This observation in conjunction with reports on the effects of hydrazine intoxication on carbohydrate metabolism prompted an investigation of the effects of MMH, UDMH, or  $N_2H_4$  on the utilization of arbitrarily selected saccharides and compounds involved in intermediary metabolism as a means of elucidating mechanism of action. An *Enterobacter cloacae* strain called D-31 showed the ability to develop (mutate into) hydrazine-resistant strains that survived hydrazine, MMH, or UDMH exposure much better than did the average population from which they were derived [764–767].

When testing the toxic effects of hydrazines on the growth dynamics and early death rates of soil microorganisms, the order of toxicity was  $N_2H_4 > MMH > UDMH$  [766–768]. The bacterial response, measured turbidimetrically in a mineral salt

medium, was a delay in the onset of logarithmic growth, with  $\geq 0.05$  ppm  $\text{N}_2\text{H}_4$  exerting an inhibitory effect. Responses were dose dependent and suggested a two-phase mechanism, possibly involving a bactericidal and a bacteriostatic effect. An *Enterobacter cloacae* strain called D-31 exposed to 10 ppm hydrazine, 20 ppm MMH, or 50 ppm UDMH showed the ability to develop hydrazine-resistant strains that survived hydrazine, MMH, or UDMH exposure much better than did the average population from which they were derived [769, 770]. The increase in final growth yield when D-31 adapted to 20 ppm MMH or 50 ppm UDMH is not yet completely understood. It appears to be selective only, rather than both selective and inductive. As hydrazine is actually produced as an intermediate in some nitrogen-fixing bacteria, the breeding of hydrazine-resistant bacteria or bacteria that thrive on hydrazine should be no surprise. The following explanations were suggested: **(1)** a bactericidal effect that significantly reduced the inoculum concentration; **(2)** as the culture ultimately resumed a normal growth pattern, the degradation of the fuels to non-toxic substances, or to an ineffective concentration; and **(3)** an adaptive mechanism that enabled the organism to overcome the inhibitory effects.

The metabolism of soil bacteria exposed to MMH was further elucidated by isotope labeling [771]. In studies with  $^{14}\text{CH}_3\text{NHNH}_2$ , the majority of the  $^{14}\text{C}$  trapped in the metabolic products in the off-gassing from soil bacteria cultures was in the form of  $^{14}\text{CO}_2$ . At concentrations from 10 to 100  $\mu\text{g/g}$ , MMH did not have any toxic effects on soil respiration or on soil bacterial or fungal populations. Strains of *Achromobacter* sp. that had a high capacity for hydrazine digestion also had a good appetite for MMH. Soil respiration (total  $\text{CO}_2$  evolution) in hydrazine-treated soils was initially inhibited, and the extent of inhibition was proportional to the initial hydrazine concentration (0, 250, and 500  $\mu\text{g/g}$  tested) [772]. Bacterial populations were also reduced initially, but fungal populations were not affected. MMH at concentrations ranging from 10 to 500  $\mu\text{g/g}$  did not inhibit soil respiration. Biological degradation of MMH is slow in comparison with abiotic autoxidation.

### 11.13 MMH Leakage and Spill Incident History

Thermal blankets are made from Mylar with vapor-deposited gold coatings to maximize reflection, and keep the heat in the spacecraft to prevent the propellants from freezing while in orbit. Accidental MMH spills on thermal blankets caused severe damage and ignition in air [773, 774], a small quantity (“a cup full”) of MMH accidentally leaked on a thermal blanket made of gold-coated Mylar film in the STS right OMS pod (RV01) of Columbia (OV-102) and auto-ignited in air. Technicians had unknowingly opened a line that contained a small amount of liquid MMH. Apparently, instructions had been given to the technicians to remove the blankets and install spill protection, but this was not completed and it was not incorporated into the procedure. The gold foil of the MLI blanket acted as a catalyst while the blanket batting absorbed and con-

centrated the released MMH. The cause of the fire was a result of the ventilated surface area creating the correct conditions for combustion of MMH. The batting acted as an insulator effectively containing the heat of the reaction, transferring the heat back to the MMH, and allowing the temperature to increase to the boiling temperature of MMH ( $360.6\text{ K} = 87.5^\circ\text{C} = 189.5^\circ\text{F}$ ). Ignition of the blanket followed once the vapor fumes reached the auto-ignition temperature of MMH ( $194^\circ\text{C} = 382^\circ\text{F}$ ). A technician used nearby flame-retardant coveralls to extinguish the flames. It was later determined that MMH and gold are not compatible. MMH dissolved the polymer film and caused damage to the thermal blanket. In a laboratory experiment after the accident, the temperature rise when MMH was spilled onto a thermal blanket in atmospheres of different oxygen content was proportional to the oxygen concentration. No warming was observed under nitrogen. The cause of ignition appeared to be the oxidation of MMH catalyzed by finely divided gold. Thermal blankets are made from Mylar or Kapton with vapor-deposited gold coatings to maximize reflection, and to retain the heat in the spacecraft to prevent the propellant from freezing.

When examining the safety of lifting the MINUTEMAN-III upper stage out of missile silos during decommissioning, there was some concern about auto-ignition of MMH vapors from liquid MMH accidentally spilled into missile silos [775].

In a different environment, part of MMH leaked into the vacuum of outer space freezes and may cluster around the leak site. The frozen MMH will slowly melt and sublime [776].

#### 11.14 Olfactory Threshold of MMH

There is a wide discrepancy in reported olfactory threshold values for MMH and the other hydrazines. Several sources agree that one should not rely on the odor of hydrazines as a warning for imminent acute or subacute exposure because it may cause olfactory fatigue. Also, the olfactory threshold is far above the established safe levels. Table 49 summarizes the reported olfactory threshold of hydrazines in comparison with former and current ACGIH TLVs. Methylhydrazines have a more distinct fishy odor, although it would be difficult to differentiate them from methylamine or dimethylamine, common constituents of fish degradation products [777].

The odor threshold levels for UDMH and  $\text{NO}_2$  have been generally quoted at 6 to 14 parts per million (ppm by volume) for UDMH and 5 ppm for  $\text{NO}_2$ . Seven years of field experience by propellant loading personnel have indicated that the actual odor thresholds are considerably below these literature values [779]. As odor threshold levels are used by safety and operating personnel at Cape Kennedy as an indication of exposure, it was considered appropriate to evaluate this field experience. On the basis of these data and the results of some controlled studies, it was concluded that the actual odor thresholds are 0.5 ppm or less for  $\text{NO}_2$  and less than 0.3 ppm for UDMH.

**Table 49:** Olfactory threshold and exposure limits of methylhydrazine in comparison with other hydrazines.

| Type of data        | Hydrazine         | References     | MMH               | References      | UDMH              | References     |
|---------------------|-------------------|----------------|-------------------|-----------------|-------------------|----------------|
| Olfactory threshold | 69–83<br>3–4      | [778]<br>[672] | 1–3<br>—          | [672, 778]<br>— | <0.3<br>6–14      | [779]<br>[672] |
| ACGIH-TLV (1998)    | 0.01 (skin)<br>A3 | —              | 0.01 (skin)<br>A3 | —               | 0.01<br>(skin) A3 | —              |

ACGIH = American Conference of Governmental Industrial Hygienists, TLV = threshold limit value

In a human volunteer test with six recruits being exposed to 30, 50 or 90 ppm MMH in air, the 30-ppm exposure was described by most individuals as “easily noticeable moderate intensity” and “strong highly penetrating” [780]. 50 or 90 ppm produced only faint to moderate irritation.

### 11.15 Epidemiology of Workers Potentially Exposed to MMH

All three hydrazines: hydrazine itself, MMH, and UDMH were implicated in an epidemiological, retrospective study of causes of death among former workers at a large aerospace company in California [781, 782]. The purpose of the study was to estimate the effects of occupational exposures to selected chemicals on cancer mortality among nuclear and aerospace workers who were employed at Rocketdyne/Atomics International between 1950 and 1993. The results of this retrospective cohort study suggested that exposure to hydrazine or other chemicals associated with the same jobs at rocket-engine test stands increased the risk of dying from lung cancer and possibly other cancers [783, 784]. However, the hydrazine chemicals were just a few of several other chemicals and adverse conditions that these workers might have been exposed to while working in various jobs in the defense and aerospace industry. Any one of these other chemicals could have caused the observed effects and hydrazine(s) cannot be singled out as the sole cause. There were no records of actual working place concentrations of hazardous vapors in the air that could be correlated with the effects observed in victims several decades later.

A similar retrospective cohort mortality study of 8372 Rocketdyne workers employed 1948 to 1999 at the Santa Susana Field Laboratory came to a different conclusion [785]. Non-significant associations were seen between lung cancer and hydrazines, and stomach cancer and years worked as a test stand mechanic. No trends over exposure categories were statistically significant. It was concluded that work at the rocket engine test facility or as a test stand mechanic was not associated with a significant increase in cancer mortality overall or for any specific cancer.

## 11.16 Maximum Allowable Exposure Limits for MMH Vapors

### 11.16.1 Long-Term Exposure Limits for MMH

Permissible Exposure Limits (PELs) for MMH vapors in places of employment are established by the US Occupational Safety and Health Administration as published in 29 Code of Federal Regulations Part 1910.1000. Table Z1A of that standard lists several hundred controlled chemicals, including MMH. The very first list published by OSHA in response to the Occupational Safety and Health Act of 1970 simply adopted the existing ACGIH TLVs from the 1968 booklet. The TLV for hydrazine in those days was 1 ppm, and there were no ill effects reported in the working population during the decades while this limit was in effect. The PEL is an enforceable government-imposed limit, but the ACGIH TLV is a guideline recommended by a professional organization. Table Z1A includes 613 chemicals. Table Z2 includes 21 chemicals, but none of the hydrazines. For each chemical, it lists a transitional PEL, a TWA, STEL, and a ceiling limit C that may not be exceeded even if the exposure is compensated for by exposure to zero contamination for the rest of the work shift. In addition, several chemicals, including all hydrazines, have a “skin” notation. The TWA is the employee’s average airborne exposure in any 8-h work shift of a 40-h work week, which shall not be exceeded. A TWA is a calculation that combines exposure times and concentrations measured throughout the work shift into a single concentration, which is often compared with the TLV to see if the facility is in compliance or not. The short-term exposure limit (STEL) is the employee’s 15-min TWA exposure, which shall not be exceeded at any time during a work day unless another time limit is specified in a parenthetical notation below the limit. PELs from the most recent version of Table Z1A are summarized in Table 50. The most recent version of Table Z1 is available on the OSHA web site [786].

National Academy of Sciences/National Research Council (NAS/NRC) Subcommittee on Certain Interim Acute Exposure Guideline Level (AEGl) values were published in the Federal Register of 30 October 1997 (62 FR 58840-58851). These chemicals included: aniline, 1,1-dimethylhydrazine, 1,2-dimethylhydrazine, fluorine, hydrazine, and methylhydrazine.

**Table 50:** Time-weighted average and short-term exposure limits.

|           | Transitional 8-h PEL <sup>a</sup> |                   |      | TWA |                   |
|-----------|-----------------------------------|-------------------|------|-----|-------------------|
|           | ppm                               | mg/m <sup>3</sup> | Skin | ppm | mg/m <sup>3</sup> |

PEL = public emergency limit, TWA = time-weighted average

<sup>a</sup> Per 29CFR 1910.1000 Table Z1A Data, January 2017 Revision

The most widely accepted TLVs are those established by the ACGIH. The definition for TLV reads: “Threshold limit values refer to airborne concentrations of substances and represent conditions under which it is believed that nearly all workers may be repeatedly exposed to day after day 8 h/day, 40 h/week without adverse effect.” Three series of ACGIH publications are particularly useful in establishing and maintaining safe working conditions at places of employment (regardless if the workplace contains hydrazines or not): The annually updated pocket-sized TLV booklet, for instance, the 2017 issue [787], the little more detailed *Guide to Occupational Exposure Values* [788], and the most detailed loose-leaf issue of *Documentation of the Threshold Limit Values and Biological Exposure Indices*, now in five ring binders that as of 2017 was in its seventh edition, a five-volume set, are the standard reference sources in this field, updated periodically with supplements [789, 790]. The 7<sup>th</sup> Edition Documentation summarizes and evaluates the scientific data from which its TLV<sup>®</sup> or BEI<sup>®</sup> values are derived. Individual sections from this collection are downloadable for MMH [791] and UDMH [792].

The NIOSH REL for MMH is 0.04 ppm (0.08 mg/m<sup>3</sup>) for a 2-h maximum excursion and a skin, ceiling, and suspect carcinogen notation. The OSHA PEL is 0.2 ppm (0.35 mg/m<sup>3</sup>) with a skin notation. See also the MAK-Collection for Occupational Health and Safety [793].

### 11.16.2 Emergency Exposure Limits

Emergency exposure limits for hydrazines were established by the Committee on Toxicology, National Research Council, National Academy of Sciences (NAS) and defined as follows: “The Emergency Exposure Limit for short-term exposure to an airborne contaminant is a concentration which, when inhaled for a specified single brief period, rare in the lifetime of an individual, is believed not to result in a period of disability or interfere with the performance of his assigned task.”

The EEL was established for healthy young males under close medical supervision. Emergency exposure limit data are available only for a fraction of all those chemicals for which TLVs were established. Limited data are available for methylhydrazines. Emergency Exposure Limits for hydrazines as recommended by the NAS-NRC are listed in Table 51 along with the TLVs [794, 795]. As can be seen from this table, the ratio between EEL (10 min.) and TLV valid at that time varies from 200 to 30, depending on the fast-acting nature of the compound.

It is obvious that exposure limits undergo periodic updates and revisions, depending on additional toxicity data becoming available, and depending on the risk that is considered acceptable for military service personnel, government employees, industry workers, or the general public. This table will need to be updated periodically.

For a decade after MMH was first introduced into the inventory, EEL values for MMH had been based on minimal information consisting primarily of acute effects, but the acute effects of MMH are seen only at lethal or supralethal dose levels. In or-

**Table 51:** Olfactory threshold and exposure limits for methylhydrazine.

| Type of data        | MMH concentration, ppm by volume | References                   |
|---------------------|----------------------------------|------------------------------|
| Olfactory threshold | 1–3                              | [672, 778]                   |
| ACGIH-TLV (1981)    | C 0.2 (skin)                     | ACGIH                        |
| ACGIH-STEL (1981)   | —                                |                              |
| ACGIH-TLV (1998)    | 0.01 (skin) A3                   |                              |
| NRC-EEL, 10 min     | 90                               | [796]                        |
| EEL, 10 min         | 10                               | [797]                        |
| NRC-EEL, 30 min     | 30                               | [796]                        |
| EEL, 30 min         | 7                                | [797]                        |

| EEL, 60 min         | 3                                | [797]                        |
| NRC-STPL, 10 min    | 9                                | Committee on Toxicology 1974 |
| NRC-STPL, 30 min    | 3                                |                              |
| NRC-STPL, 60 min    | 1.5                              |                              |
| NRC-PEL, 10 min     | 90                               |                              |
| NRC-PEL, 20 min     | 30                               |                              |
| NRC-PEL, 30 min     | 15                               |                              |

ACGIH = American Conference of Governmental Industrial Hygienists; TLV = threshold limit value, STEL = short-term exposure limit, EEL = emergency exposure limits, NRC = National Research Council, STPL = short-term public limit, PEL = public emergency limit.

der to fill this data gap, a series of experiments were conducted to define an atmospheric concentration of MMH that would produce no irreversible injury and no clinical evidence for CNS injury [798, 799]. Dogs, monkeys, rats, and mice were exposed to MMH vapors for periods of 15, 30, and 60 min. to concentration  $\times$  time (CT) doses of 900 ppm-min. The 900-ppm-minute CT dose of MMH, which was 25% of the LC concentration for the most susceptible animal species tested, included a safety margin below the lowest dose reported to produce marginal decrement of performance in trained cats and monkeys. In view of the negative finding in all species exposed to the 900 ppm-minute CT dose level of MMH, an upward revision of previous EEL values was recommended.

Human volunteer tests in exposure chambers in which only the heads of the human subjects were exposed to 90 ppm MMH for 10 min. under close medical supervision indicated that the 10-min. EEL set at this limit was properly selected [780]. Ninety ppm MMH was more irritating than ammonia at the 30-ppm level, but less irritating than ammonia at the 50-ppm level. Pre- and post-exposure clinical tests showed that the individuals did not suffer any permanent adverse effects as the result of this test.

### 11.16.3 Immediately Dangerous to Life and Health Limits

In addition to establishing an EEL, some agencies have begun to collect information and publish information on the Immediately Dangerous to Life and Health (IDLH) con-

**Table 52:** Immediately dangerous to life and health limits for hydrazines.

| Compound        | Original IDLH (SCP), ppm | Revised IDLH, ppm |
|-----------------|--------------------------|-------------------|
| Hydrazine       | 80                       | 50                |
| MMH             | 50                       | 20                |
| UDMH            | 50                       | 15                |

| Ethanol         | 15000                    | 3300              |
| Ammonia         | 500                      | —                 |

IDLH = Immediately Dangerous to Life and Health, SCP = standard completion program

Data source: [800, 801]

centrations of fast-acting acute poisons. The NIOSH/CDC home page has IDLH information posted for hydrazine and MMH. The recommended limits are summarized in Table 52 in comparison with several other commonly used hazardous chemicals

The National Advisory Committee for Acute Exposure Guideline Levels (NAC/AEGL Committee) for Hazardous Substances of the NRC used various criteria to develop AEGL limits for the general population (Table 53). AEGL-3 is the airborne concentration of a substance at or above which it is predicted that the general population, including “susceptible” but excluding “hypersusceptible” individuals, could experience life-threatening effects or death. This estimate of a threshold for

**Table 53:** Proposed Acute Exposure Guideline Level (AEGL) values for alkylhydrazines.

| Compound | Classification limit | 30-min.                            | 1-h                               | 4-h                                 | 8-h                                 | Endpoint                                                                            |

|          | AEGL-2               | 2 ppm<br>(3.8 mg/m <sup>3</sup> )  | 1 ppm<br>(1.9 mg/m <sup>3</sup> ) | 0.2 ppm<br>(0.4 mg/m <sup>3</sup> ) | 0.1 ppm<br>(0.2 mg/m <sup>3</sup> ) |                                                                                     |
|          | AEGL-3               | 6 ppm<br>(11.3 mg/m <sup>3</sup> ) | 3 ppm<br>(5.6 mg/m <sup>3</sup> ) | 0.7 ppm<br>(1.1 mg/m <sup>3</sup> ) | 0.3 ppm<br>(0.6 mg/m <sup>3</sup> ) | 1-h LC <sub>50</sub> of 82 ppm reduced 3-fold to estimate a lethality threshold     |
| UDMH     | AEGL-1               | N/A                                | N/A                               | N/A                                 | N/A                                 | N/A                                                                                 |
|          | AEGL-2               | 6 ppm<br>(14.7 mg/m <sup>3</sup> ) | 3 ppm<br>(7.4 mg/m <sup>3</sup> ) | 0.8 ppm<br>(2 mg/m <sup>3</sup> )   | 0.4 ppm<br>(1 mg/m <sup>3</sup> )   | Behavioral changes and muscle fasciculations in dogs exposed to 360 ppm for 15 min. |
|          | AEGL-3               | 22 ppm<br>(54 mg/m <sup>3</sup> )  | 11 ppm<br>(27 mg/m <sup>3</sup> ) | 3 ppm<br>(7.4 mg/m <sup>3</sup> )   | 1.5 ppm<br>(3.7 mg/m <sup>3</sup> ) | Lethality threshold of 327 ppm for 1 h estimated from 1-h LC <sub>50</sub> in dogs  |

Data source: National Research Council, National Advisory Committee, [804–806]

irreversible effects was justified because of the absence of exposure–response data related to irreversible or other serious, long-lasting effects and the dose–response relationship indicated by the insufficient data that were available on MMH or UDMH. For AEGL-3 of MMH, lethality data (1-h LC50 of 82 ppm) for squirrel monkeys [673, 674] was adjusted using a modifying factor of 3 to estimate a lethality threshold (27 ppm). The AEGL-3 for UDMH was derived from the 1-h LC50 (981 ppm) for UDMH in dogs [802, 803].

In a 2001 re-evaluation of AEGL data for MMH, the 10-min. AEGL-3 was set at 16 ppm and the 10-min. AEGL-2 value was derived from a 3-fold downward adjustment of the 10-min. AEGL-3 value and was set at 5.3 ppm [807]. In a 2001 re-evaluation of AEGL data for UDMH, the 10-min. AEGL-2 was set at 18 ppm and the 10-min. AEGL-3 level was set at 65 ppm [808]. For a historical perspective of rationales for establishing EELs, see also Smyth [797].

### 11.17 Long-Term Exposure in Closed Environments

The 8-h/day, 40-h/week exposure cycles for the working population are quite different from those of astronauts working and living in space stations or navy personnel in submarines. A different set of criteria has to be generated for these conditions. Spacecraft Maximum Acceptable Concentrations (SMACs) were established by NASA for potential contaminants in closed environments [809]. A draft table of derived SMACs was to be submitted to the National Research Council Committee on Toxicology for review before implementing the new limits on all future space flights [810]. For MMH, SMAC limits of 0.002 ppm were proposed for all exposure durations, because a different metabolic mechanism/target organ is involved than with hydrazine  $N_2H_4$ . Although one would intuitively expect the toxicities of hydrazine and MMH to be similar, NASA toxicologists arrived at quite disparate SMAC values.

## 12 Environmental Effects of MMH

In view of the growing concern of the public about the environmental effects of hazardous chemicals and in view of increasing legislative action on the control of chemical hazards, this book would be incomplete without a section on the environmental effects of MMH. This information can generally be derived from other paragraphs on toxicity and autoxidation, but it is worthwhile considering MMH chemistry from the standpoint of an environmentalist.

Fortunately, and in contradistinction to polychlorinated biphenyl, dioxin, or dichlorodiphenyltrichloroethane (DDT), there is little to be said about the endurance of hydrazine and hydrazine derivatives because they degrade so rapidly under the influence of air (oxygen), light, and soil bacteria. This is one of the most distinct

advantages of hydrazine-derived chemicals in numerous agricultural and industrial applications such as pesticides, boiler feedwater treatments, or anticorrosion additives. The biodegradability of hydrazine derivatives is one of the reasons why some hydrazine-based pesticides have been chosen to replace more persistent, chlorinated organics (DDT) that may accumulate in the food chain and/or are suspected endocrine disruptors.

### 12.1 Sources of Information on Environmental Toxicity of MMH

Under the sponsorship of the US Air Force Civil and Environmental Engineering Development Office (CEEDO, later AFESC-ESL) at Tyndall AFB, FL, a series of conferences on the environmental chemistry of hydrazine fuels were held in 1977, 1979, and 1987. The proceedings from these three meetings [811–813] constitute a valuable resource for studying the environmental effects of hydrazine fuels.

During the period 1970 through 1985, the US Air Force Medical Research Laboratory hosted a series of *Annual Conferences on Environmental Toxicology*. Some of these conferences contained several individual papers on hydrazines, although several conferences did not deal with hydrazines at all.

The US EPA has issued several *Health and Environmental Effects Profiles* for hydrazine and UDMH, but not for MMH. Howard's *Handbook of Environmental Degradation Rates* [814] gives data for a large number of chemicals, including MMH, UDMH, SDMH, hydrazine, and NDMA. The environmental chemistry of hydrazines continues to receive interest, as indicated by summary and review publications [815].

### 12.2 Aquatic Toxicity of MMH

The toxicity of hydrazine, MMH, and UDMH was measured in static LC<sub>50</sub> estimations using two freshwater fish, golden shiners, and channel catfish, and two invertebrates, amphipods and isopods. The data did not clearly indicate that the invertebrates were more sensitive than the fish to the chemicals and that the relative toxicities of the hydrazines were different. The aquatic toxicity LC<sub>50</sub> values of several hydrazines to several species are compiled in Table 54. The results in the first four rows of the table are the result of tests run in five different concentrations, ranging from 0.5 to 100 ppm. The catfish were most sensitive to hydrazine itself, less to MMH, and much less to UDMH.

#### 12.2.1 Aquatic Toxicity of MMH to Algae

In evaluating the toxicity of hydrazines to several species of unicellular green algae (*Selenastrum capricornutum* [S.], *Dunaliella tertiolecta* [D.], *Chlorella stigmatophora* [C.]), and trying to establish a dose–response relationship, hydrazine was

**Table 54:** Aquatic toxicity of hydrazines toward fish and invertebrates.

| Species                       | N <sub>2</sub> H <sub>4</sub> | MMH  | UDMH    | References |
|-------------------------------|-------------------------------|------|---------|------------|
| <i>LC50 (ppm)</i>             |                               |      |         |            |
| Amphipods                     | 0.04                          | 1.2  | 4.7     | [816]      |
| Isopods                       | 1.3                           | 0.8  | 12.4    | [816]      |
| Channel catfish               | 1.0                           | 3.5  | 11.3    | [816]      |
| Golden shiner                 | 1.1                           | 2.3  | 34      | [816]      |
| <i>LC50 (mg/L)</i>            |                               |      |         |            |
| Fathead minnows 96-h bioassay | 4.5                           | 1.22 | 0.35    | [318]      |
| Daphnia 48 h                  | 0.1 to 1.0                    | <5   | 5 to 10 | [318]      |

found to be the most toxic, MMH less, and UDMH least toxic. The objective of the studies was to determine the no-effect safe concentration (SC) and a median effect concentration EC<sub>50</sub> concentration, which causes a 50% reduction of growth of the algae. Three types of freshwater were tested: oligotrophic (10% Standard Algal Assay Medium = SAAM nutrients), intermediate (33% SAAM), and eutrophic (100% SAAM). Slightly higher concentrations were tolerated under eutrophic as opposed to under oligotrophic conditions. MMH was less toxic, with an SC of 0.2 µL/L tolerated under spill conditions; UDMH was even less toxic, with an SC between 1 and 3 µL/L. Hydrazine was approximately 200 times more toxic to algae than MMH or UDMH. The toxicity of the compounds studied was directly correlated with compound stability during the static (no replenishment) bioassays. Hydrazine, the most stable in the various algal growth media, was the most toxic, whereas UDMH, the least stable, was also the least toxic (Table 55). Aerozine-50 aquatic toxicity was identical to that of hydrazine, its most toxic constituent [817].

**Table 55:** Toxicity of hydrazines to algae in freshwater and seawater.

| Water type              | Test organism           | Initial concentration of compound, µL/L<br>(Based on sixth day EC <sub>50</sub> counts) |                  |     |                  |      |                  |
|-------------------------|-------------------------|-----------------------------------------------------------------------------------------|------------------|-----|------------------|------|------------------|

EC = effect concentration, SC = safe concentration

Data source: [818]

Algae toxicity testing with hydrazine, MMH, and UDMH was conducted in seawater with salinities of 16, 24, and 35 ppt [819]. There was little difference between the SC and EC50 values obtained at various brackish and seawater salinity levels. For *aufwuchs* benthic biomass, MMH was much more toxic than hydrazine, because the no-effect level was between 0.01 and 0.15 mg MMH/L. With UDMH, there was a significant reduction in the photosynthesis index for *aufwuchs* in the tanks containing initial UDMH concentrations of 10 and 93 mg/L.

### 12.2.2 Aquatic Toxicity of MMH to Bacteria in Water

This section is closely related to the toxicity of MMH toward bacteria in soil, which is discussed in more detail in Section 12.5. Much of the work on the toxicity of MMH toward water-borne bacteria stems from the concern for the continued health and performance of active sludge waste treatment systems in the event that a MMH spill should be washed into the sewer.

The toxicity of hydrazine, MMH, and UDMH to four enriched bacterial cultures: *Nitrobacter*, *Nitrosomonas Nitrobacter*, anaerobic bacteria, and denitrifying bacteria was measured in incubators [761–763, 820]. In addition, the metabolic digestion of hydrazine by *Nitrosomonas Nitrobacter* was examined. The toxicity studies utilized batch bioassay methods with response measured in terms of substrate metabolism rates as measured by gas evolution. Batch tests were run for 6 days with hydrazine, 10 days with MMH, and 14 days with UDMH. The results showed that hydrazine produced a 50% reduction in metabolism rate for *Nitrobacter*, *Nitrosomonas Nitrobacter*, anaerobic bacteria, and denitrifying bacteria at concentrations of about 15, 165, 100, and 100 mg/L respectively; MMH at 15, <1, 75, and 10 mg/L respectively; and UDMH at 1800, 35, 2300, and 12500 mg/L respectively. With anaerobic bacteria, recovery was observed for the three lowest hydrazine doses at 2.7, 13.3, and 133 mg/L. When recovery occurred between days 2 and 5, the accumulated feed was rapidly digested and the daily gas production would temporarily exceed that of the controls. Very high doses of UDMH were required to produce significant toxicity for denitrifying bacteria. Hydrazine was the least toxic of the three fuels to *Nitrosomonas*. *Nitrosomonas* was largely unaffected by hydrazine doses that proved toxic to other bacteria. The metabolism study used <sup>15</sup>N-labeled hydrazine sulfate followed by mass spectrographic analysis of the captured gas. *Nitrosomonas* were found to metabolize some hydrazine to nitrogen gas on a short-term basis, but could not metabolize MMH or UDMH. It was concluded that spills of any of these three fuels could be expected to seriously disrupt the natural bacterial balance in the aquatic environment. Use of biological waste water treatment for detoxification of these three fuels was not recommended.

### 12.2.3 Aquatic Toxicity of MMH to Invertebrates, Amphibians, and Crustaceans

Some data on toxicity of MMH to invertebrates, amphibians, and crustaceans were already included in Table 54. A bioassay using two freshwater invertebrates, isopods (*Asilidae*) as well as amphipods (*Hyaella azteca*), and two species of fish (*Ictalurus punctatus* Rafinesque, channel catfish, and *Notemigonus crysoleucas*, golden shiner) and exposing them to hydrazine, MMH, or UDMH showed that hydrazine was the most toxic of the three compounds tested [816]. Hydrazine was more toxic than MMH or UDMH to amphipods, and there was no difference between MMH or UDMH. A study was conducted to determine the LC50 of hydrazine to bay mussels (*Mytilus edulis*) and the mud flat crab (*Hemigrapsus oregonensis*) [819]. For crabs and mussels, it was not possible to calculate an LC50 for MMH, because there was 100% mortality at 0.15 mg/L and no mortality at 0.012 mg/L [821]. Aquatic bioassay studies with fresh or partially ozonized MMH or UDMH with *Daphnia* showed an EC50 of 0.1 to <10 mg/L [320, 321].

### 12.2.4 Aquatic Toxicity of MMH to Fish

The acute toxicity of hydrazine, MMH, UDMH, and Ae-50 to the common guppy (*Lebistes reticulatus*) was tested in three to four static, unaerated bioassays, each using hard and soft water [822, 823]. The LC50 after 96 h of exposure differed significantly depending on the hardness of the water used. For example, the hard-water/soft-water LC50 ratio data were as follows: MMH, 3.26/2.58; UDMH, 10.1/26.5; and Ae-50, 2.25/1.17 mg/L. Hydrazine was the most toxic compound and UDMH the least toxic to common guppies. Hydrazine was significantly more toxic in soft water than in hard water, whereas UDMH was the opposite. The results of bioassays in which survival times of fish pre-exposed to these compounds were compared with those previously unexposed, along with other observations, indicate that the toxic effects of the hydrazines are cumulative.

The 336-h LC50 of MMH for stickleback was 0.01 mg MMH/L, as opposed to 1.1 mg hydrazine/L for hydrazine N<sub>2</sub>H<sub>4</sub> [821, 824]. Because MMH concentrations decreased to 65% within 6 h, in one series the MMH concentration was maintained by renewing the solutions daily. No fish survived the first day of exposure in a jar containing an initial MMH concentration of 3.2 mg/L [819]. In another jar containing an initial MMH level of 1 mg/L, there were no survivors after 49 h. The MMH LC50 for duplicate samples were 1.4 and 1.9 mg/L at 24 h, 0.6 and 0.46 mg/L at 48 h, and 0.32 and 0.4 mg/L at 96 h. In one test, all fish died within 96 h in tanks that contained initial UDMH concentrations of 10 and 19.3 mg/L. There was no detectable excess of free UDMH in the tank within 7 h of its introduction. It was also noted that in a static system, simulating a spill into a lake or pond, UDMH stratified on the surface owing to its lower density. In a real spill, the organisms staying near the surface would be more seriously affected than bottom dwellers.

Aquatic bioassay studies with fathead minnows showed LC50 values of 4.5, 1.2, and 0.35 mg/L for hydrazine, MMH, and UDMH respectively [321, 554]. As hydrazine and alkylhydrazines react with dissolved oxygen, LC50 or EC50 could be lower in practice.

### 12.3 Environmental Fate of MMH in Air

The rate of evaporation of MMH and the other two propellant hydrazines was measured in Petri dishes in the laboratory under carefully controlled climatic conditions [825, 826]. Table 56 summarizes some of the evaporation rate and half-life data of the three most commonly used hydrazines. As one can see, there is a gradual increase in the rate of evaporation as well as half-life time from hydrazine to MMH and from MMH to UDMH. The investigators did not realize that hydrazine mass loss by evaporation in ambient air is partially counteracted by carbon dioxide absorption, which causes a mass gain.

**Table 56:** Rate of evaporation and environmental decay of hydrazine fuels.

| Compound  | Evaporation rate <sup>a</sup> ,<br>mg cm <sup>-2</sup> min <sup>-1</sup> | Half-life time |             |
|-----------|--------------------------------------------------------------------------|----------------|-------------|
|           |                                                                          | Air, h         | Water, days |
| Hydrazine | 0.49                                                                     | 1.10           | 7           |
| MMH       | 1.7                                                                      | 2.7            | 10          |
| UDMH      | 13                                                                       | 100            | 10          |

<sup>a</sup> In stagnant air at 291–294 K, based on data from a 177-cm<sup>2</sup> dish

Data source: [825, 826]

Reactions of MMH with selected species of interest that are found in the environment, mostly in the high atmosphere, have been investigated [827]. Included were aqueous phase reactions that can occur in atmospheric aerosols, rain drops, groundwater, or soils in contact with groundwater, as well as selected gas phase reactions. Reactants included oxygen and hydrogen peroxide (both reactants in the presence and absence of catalysts), ozone, nitrous acid, sulfur dioxide, and acetone (as a model for environmental ketones and aldehydes). Rate constants for the reactions have been determined, or upper limits set. By far the fastest reactions measured were those involving the hydrazines and ozone with (second-order) rate constants up to  $2.4 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1}$ .

#### 12.3.1 MMH Atmospheric Decay Studies in Plastic Foil Lined Chambers

A study was designed to experimentally evaluate the atmospheric fate of UDMH, MMH, and unsubstituted hydrazine N<sub>2</sub>H<sub>4</sub> in laboratory chambers under controlled

conditions [828]. Because of the need for detailed information on the gas-phase chemistry of propellant hydrazines, the following specific supporting studies were undertaken: flash photolysis-resonance fluorescence measurements of the absolute rate constants for the reaction of hydrazines with hydroxyl (OH) radicals; a study of the rates and products of the dark reactions of ozone with hydrazine, MMH, and UDMH; and an investigation of the  $\text{NO}_x$ -photooxidation of these same hydrazines under simulated atmospheric conditions. The latter two studies were conducted using a 30000-L outdoor irradiation chamber equipped with a 10-m base path optical system coupled to an FTIR spectrometer. The results of the studies showed that, upon release into the atmosphere, all three of the hydrazines investigated could be rapidly consumed by reaction either with ozone or with OH radicals present in the atmosphere, depending on the nature of the atmosphere into which the emissions occur. With respect to reaction with OH, the tropospheric half-life for hydrazine is expected to range from 1 h in polluted urban atmospheres to up to 3 to 6 h in unpolluted atmospheres, with substituted hydrazines being consumed at about the same rate. With respect to reaction with ozone, the half-life for unsubstituted hydrazine would range from less than 10 min. during ozone pollution episodes to less than 2 h in the natural troposphere, with the half-lives for MMH and UDMH being at least a factor of 10 shorter. Therefore, under most conditions, reaction with ozone will be the most efficient mode of degradation of hydrazines released into the high atmosphere. A major release of MMH in an area of high ozone pollution could subject nearby downwind regions to possibly significant levels of methyl hydroperoxide, methyldiazene, or diazomethane. A similar scenario for UDMH would form nitrosamines, which in turn react in sunlight to form the relatively more stable nitramines.

Methylhydrazine and atmospheric ozone formed  $\text{CH}_3\text{OOH}$ ,  $\text{H}_3\text{CN}=\text{NH}$ , formaldehyde,  $\text{H}_2\text{CN}_2$ , and  $\text{H}_2\text{O}_2$  with lower yields of  $\text{CH}_3\text{OH}$ ,  $\text{NH}_3$ , and  $\text{N}_2\text{O}$ .  $\text{H}_3\text{CN}=\text{NH}$  already present in a reacted mixture rapidly disappeared after more ozone was added. Formaldehyde was observed only in mixtures with an excess of ozone, not in mixtures with an excess of MMH [829].

A 4-year research program at NASA WSTF resulted in a very detailed and very thorough report of reaction rates of hydrazines in air under various conditions [830]. The objective of the study was to provide further insight into the mechanisms by which propellant hydrazines decompose in the atmosphere. It was difficult to eliminate interference owing to wall permeation from the plastic foil-lined test chambers. Four different methods were used: a static environmental chamber [302], a packed microreactor, an atmospheric pressure laminar flow reactor [304], and FTIR adsorption spectra of surface-adsorbed species. In one series of tests, using a 6515-L Teflon film-lined chamber made of 0.013-cm (5-mil) FEP foil with a surface : volume ratio of  $3.39 \text{ m}^{-1}$ , stirred with a PTFE-coated fan, the measurements were troubled by permeation. The chamber was surrounded by another polyethylene film-walled chamber at a distance of 5 cm, which could be purged with nitrogen to prevent diffusion of ambient air into the test cham-

ber. Permeation was the main mechanism for hydrazine(s) disappearance, as the rate of disappearance in nitrogen was the same as that in air. The half-life times of hydrazine, MMH, and UDMH in the Teflon chamber were 40, 19, and 60 h respectively. The presence of water (14600 ppm) or carbon dioxide (300 or 1000 ppm) accelerated the disappearance, but the two effects were not cumulative. Panels of various materials under study were inserted into the chamber to study surface-catalyzed effects. Very rapid oxidation of hydrazine occurred on corroded aluminum panels. MMH was less reactive on the corroded aluminum surfaces. The rate of MMH disappearance increased with the square of the surface area of added aluminum panels. The  $\text{Al}/\text{Al}_2\text{O}_3$  catalyzed oxidation of MMH yielded methyldiazene ( $\text{HN}=\text{NCH}_3$ ) as an intermediate and traces of methanol. The relative reactivities of hydrazine, MMH, and UDMH were 130:7.3:1 respectively.

In a packed tubular microreactor at a slightly elevated temperature in air, hydrazine was oxidized too rapidly to be measured on all metal powders and building material samples (sand, concrete, cinder blocks) [303]. The rate of MMH oxidation was slow enough to be measured, and the activity of the materials relative to CRES-304 = 1.0 could be ranked as follows: Fe 210 >  $\text{Al}_2\text{O}_3$  120 > Zn 41 > CRES-316 23 > Ti 10 > Cr 7 > Al 2 > CRES-304 1 > Ni ~ 1. Products of MMH oxidation were methanol, methyldiazene, methane, and some ammonia. UDMH proved to be much less reactive than either hydrazine or MMH. Only trace amounts of reaction products were noted, which were not identified. Trimethylhydrazine or tetramethylhydrazine were essentially unreactive under these conditions.

The laminar flow reactor consisted of a rectangular chamber made from polymethylmethacrylate plastic with four 40 × 60-mm KCl windows for multiple passage of diagnostic IR beams at different locations downstream from the injection and mixing zone [304]. Hydrazine or MMH vapor was mixed with air or ozonated air, flowed through the test section, and exhausted into a fume hood. This dynamic flow setup allowed chemical kinetic measurements at atmospheric pressure free from wall effects. The following IR bands (with absorption coefficients given in parentheses) were used to analyze for hydrazine:  $958\text{ cm}^{-1}$  ( $5.87\text{ atm}^{-1}\text{ cm}^{-1}$ ), MMH:  $888\text{ cm}^{-1}$  ( $4.69\text{ atm}^{-1}\text{ cm}^{-1}$ ), and ozone:  $1058\text{ cm}^{-1}$  ( $7.31\text{ atm}^{-1}\text{ cm}^{-1}$ ). Diffuse FTIR of hydrazines adsorbed on deuterated silica powder showed that the surface adsorption is primarily physical and that adsorbed hydrazines do not undergo molecular changes when adsorbed. In conclusion, although oxygen is the major reactive constituent of air, its homogeneous rate of reaction with hydrazines is so slow that air contaminants such as ozone or  $\text{NO}_x$  and airborne particulates have an overwhelming effect on the overall rate of hydrazine(s) disappearance. Using the rate constants derived from the laminar flow reactor, it was predicted that the half-life time of hydrazine or MMH in a moderately contaminated day-time atmosphere is less than 2 h owing to reaction with ozone and hydroxyl radicals. The presence of hydrazine may actually increase the  $\cdot\text{OH}$  and  $\cdot\text{OOH}$  free radical concentration in air.

### 12.3.2 Studies in Lined Steel Chambers

A special Teflon-lined steel chamber was built by the AFESC-ESL laboratory at Tyndall AFB in Florida and used for detailed studies of hydrazine(s) decay kinetics in air. The steel enclosure prevented ambient atmospheric oxygen from diffusing through the plastic foil into the chamber. Atmospheric decay studies in the laboratory have shown that hydrazine oxidation in air is highly dependent on the available surface area and the composition of the surface material. Because the decay rate is greatly influenced by heterogeneous reactions, one has to be careful when extrapolating from laboratory data to real ambient conditions with unconfined air spaces.

After variable results with polymer foil as a chamber wall material, a Teflon-coated, stainless steel sphere measuring 1 m in diameter was constructed at ESL as a tool for conducting studies of the atmospheric chemistry of hydrazines [831–833]. A spherical chamber shape was chosen because it had the most favorable surface:volume ratio and would help to minimize unwanted surface effects. The spherical chamber has a 15% advantage over cylindrical designs and a 24% advantage over traditional cubical smog chambers. Three cylindrical adapters measuring 25 cm in diameter were welded to the chamber, two for optics and one for sample handling. Smaller ports served for optical alignment, vacuum connections, stirring fan mount, and drain. The temperature could be controlled from 278 to 323 K (5 to 50 °C = 41 to 122 °F). The chamber could be evacuated to 0.0007 Pa (0.000005 Torr). Gas samples were introduced from an external manifold. Solid samples of various kinds could be placed into the interior of the chamber through a 30-cm (12-in) sampling port to determine their effects on gases under study. The chamber was equipped with an *in situ*, multi-pass optical system that allowed variable IR path lengths of up to 106 m (348 ft) for identification of reactants, intermediates, and products of the reactions. Adding a light source to measure hydrazine photochemical decay reactions typical for daytime releases into the atmosphere was considered. Addition of a residual gas analyzer would be useful to quantify oxygen and nitrogen concentrations as reactants and reaction products and verify low leakage rates at near-vacuum chamber pressures. Similar tests were conducted with hydrazine and UDMH vapors.

### 12.4 Environmental Fate of MMH in Water

In the absence of bacteria, in sterile water, but exposed to air and sunlight, MMH still degrades quickly. The rate of MMH degradation is dependent on water pH, temperature, hardness, other dissolved mineral content, and sunlight. Hard and soft water samples with and without the addition of MMH were examined over a 96-h period for changes in alkalinity (with two different pH indicators), pH, specific conductance, EDTA hardness, and dissolved oxygen [834]. The dissolved oxygen content changed more rapidly in hard water than in soft water.

## 12.5 Environmental Fate of MMH in Soil

Similar to problems with experiments on persistence and biological effects of spilled hydrazines in surface waters, it is very difficult to conduct soil toxicity and degradation experiments under carefully controlled conditions, because so many variables are involved [835]. Hydrazines may reversibly adsorb on soil inorganic or organic matter, become irreversibly oxidized by soil minerals, or simply decompose catalytically to nitrogen and ammonia. *A Handbook of Environmental Degradation Rates* [814] gives the following estimates summarized in Table 57 for half-life times of hydrazines in non-sterile soils. These numbers are “best estimates, based on scientific judgment, based upon estimated unacclimated aqueous aerobic biodegradation half-life” [814].

**Table 57:** Estimated half-life time of hydrazines in soil.

| Compound name | High estimate, days | Low estimate, days |
|---------------|---------------------|--------------------|
| Hydrazine     | 7                   | 1                  |
| MMH           | 24                  | 13                 |
| UDMH          | 22                  | 8                  |
| SDMH          | 28                  | 7                  |
| NDMA          | 180                 | 21                 |

Data source: [814]

It is difficult to determine adsorption isotherms of MMH and other hydrazines in soils because most of the hydrazines decompose before a complete adsorption/desorption cycle can be completed. The interaction of soils and hydrazines is very complex and depends on the type of soil (sand, clay, humus) and the oxidants present. Oxidants would be air, adsorbed air pollutants (e.g., ozone, peroxides), highly oxidized minerals, or active oxidizers produced as metabolic products by bacteria (e.g., nitrogen dioxide). The current section deals only with the abiotic degradation of hydrazines in soil. The degradation process is potentially greatly accelerated by certain types of soil bacteria. Soil percolation/adsorption tests were conducted with MMH and UDMH (0.1% solutions) through/on four different types of soils (sand, clay, organic, and one typical for Vandenberg AFB, VAFB) [311, 312]. The soil samples were mostly sandy soils with little cation exchange capacity. All soils were dried at 353 K for 24 h, which should have killed most of the soil bacteria. In soil percolation tests, fuel solutions were applied to a 200-g soil sample in a column and leached with 500 mL of water. Yellow autoxidation products interfered with subsequent colorimetric determinations. GC-MS was a more reliable method, even in the presence of autoxidation products. Table 58 summarizes the adsorption/extraction results obtained after soaking 3-g soil samples for 20 min with 30 mL of 0.002 vol.-% solutions.

**Table 58:** Adsorption/extraction results of hydrazine fuels in soil.

| Propellant | Soil    | Adsorbed, % | Extracted w. 0.1 N HCl, % | Non-recovered, % |
|------------|---------|-------------|---------------------------|------------------|
| Hydrazine  | Sand    | 1 ± 1       | 2 ± ?                     | —                |
| Hydrazine  | VAFB    | 58          | 44                        | 14               |
| Hydrazine  | Organic | 53          | 25                        | 28               |
| Hydrazine  | Clay    | 77          | 59                        | 18               |
| MMH        | Sand    | 0 ± ?       | 3 ± ?                     | —                |
| MMH        | VAFB    | 51          | 46                        | 5                |
| MMH        | Organic | 46          | 26                        | 20               |
| MMH        | Clay    | 73          | 64                        | 8                |
| UDMH       | Sand    | 0 ± ?       | 5 ± ?                     | —                |
| UDMH       | VAFB    | 31          | 20                        | 11               |
| UDMH       | Organic | 26          | 15                        | 11               |
| UDMH       | Clay    | 80          | 30                        | 50               |

Data source: [312]

No fuel interaction was observed with clean sand (as in the percolation studies), but strong effects were observed in all natural soil samples. The strongest interaction was with clay-type soils. Hydrazine and MMH were more reactive than UDMH in all soils.

Hydrazines can be adsorbed and desorbed by soil colloids in essentially unchanged form or can be irreversibly chemisorbed [836–838]. The interactions of MMH with soil constituents and with soils were examined using (1) batch/slurry techniques, (2) continuous-flow stirred reactor techniques, and (3) column extraction techniques. In addition, IR, XRD, and microcalorimetry were used to study hydrazine–soil interactions. Four different types of clays were used: montmorillonite, kaolinite, illite, and bentonite. Humic acid and fulvic acid were extracted and isolated from humus-rich soils. In the presence of clay suspensions, part of the original MMH added to the suspension was absorbed by the homoionically exchanged montmorillonite and another part was oxidized.

The environmental fate and distribution of MMH spills in the soil may depend on adsorption/desorption equilibria between MMH adsorbed in clay and MMH vapor [839]. Isotherms were obtained at 298, 308, and 318 K for the sorption and desorption of MMH by sodium-exchanged montmorillonite and kaolinite clays, and by an iron(III)-exchanged kaolinite preparation. Isotherm data were analyzed in conjunction with data from XRD diffraction and IR spectroscopy in order to investigate the sorbate–sorber interaction mechanisms. Similar isotherm analyses were carried out for the sorption of water vapor, which could be expected to compete with MMH for sorption sites. Sorption by Na<sup>+</sup>–kaolinite was essentially reversible but some hysteresis was evident in desorption from the iron clay.

Methylhydrazine and hydrazine autoxidation were studied in the presence of colloidal hematite, a common soil mineral [840]. The reaction was followed colorimetri-

cally and analyzed using sorption isotherms. Although one should think that hematite should be a good catalyst, instead it was found that autoxidation in the presence of the hematite was attenuated when compared with autoxidation in water only. This indicated that the interaction between the hydrazines and the hematite in some way protects the hydrazines by complexation, hydrogen bonding between the hydrazines and the oxygens, or the first hydration spheres, on the hematite. Environmental implications of this finding include enhanced transport of the compounds through the groundwater with the colloidal hematite as a vector, and increased residence times in the environment. The specific interaction between the hydrazines and hematite was investigated using FTIR-ATR (attenuated total reflection), enabling direct spectral analysis of the interaction and its changes with time and dependence on pH. These analyses indicated that the interaction is probably due to electrostatic interactions, including hydrogen bonding between the hydrazines and the oxygens, or the first hydration spheres, on hematite. It was found that the interaction changed with time, and that the interaction was stable to heating, and appeared to have a long lifetime, indicating a strong final interaction. Similar results were found when the FTIR-ATR was used to analyze the interaction of the hydrazines with common clay minerals. The toxicity of hydrazines on soil microflora indicated that in the absence of hematite or clay minerals, the autoxidation of the hydrazines is rapid enough that the microbes were only exposed to harmless end products. No evidence for the stimulation of microbial growth in the presence of the hydrazines was found.

## 12.6 Biodegradation of MMH

Bioremediation of MMH spills in soil may be possible only after sufficient dilution with water and only in the presence of the right type of soil bacteria and nutrients for their propagation. The same applies to spills of hydrazine or hydrazine hydrate (H-70).

Adaptive mechanisms allow some bacteria to thrive on hydrazines instead of being killed by them. Three possible adaptive mechanisms by which soil bacteria may survive inhibitory or exterminating environments are:

- (1) environmental selection of pre-existing resistant variants in a population;
- (2) mutation to resistant variants; and
- (3) induction of specific enzyme systems that counteract the effects of the toxic ingredient.

To determine if an inductive, selective, or mutation mechanism is involved in the resistance of bacteria to hydrazine fuel toxicity, the effects of  $N_2H_4$ , MMH, and UDMH on the growth kinetics of *Enterobacter cloacae* cultures that had been previously exposed to low levels of each of the fuels were studied *in vitro* [769, 770]. One concentration was selected for each fuel that was shown to increase the lag time significantly but would eventually permit the culture to grow to maximum yield. The concentrations selected

were 10 ppm for  $N_2H_4$ , 20 ppm for MMH, and 50 ppm for UDMH (ppm measured by volume, not by mass).

The toxicity of hydrazine, MMH, and UDMH were determined for mixed and uni-cultures of nitrifying bacteria, denitrifying bacteria, and anaerobic methanogenic bacteria [761–763]. MMH was more toxic than hydrazine, which was more toxic than UDMH. The toxicity level numbers were low enough to preclude biological waste treatment of these compounds.

Despite the fact that axenic bacterial cultures are inhibited by all three propellant hydrazines, it was reported that soil respiration, and total bacterial and fungal populations in soil, were not inhibited by hydrazine at concentrations of 100  $\mu\text{g/g}$  and lower. Even at 500  $\mu\text{g/g}$ , only total bacterial populations in soil were inhibited by the presence of hydrazine. Hydrazine rapidly disappeared in soil, so next to investigate was the effect of MMH on soil microbial activity and on degradation of MMH in soil [841]. Two hundred grams of soil were placed in 500-mL wide-mouth glass bottles with screw caps, and 16 mL of deionized water were added. MMH was applied to the soil samples to give concentrations of 0, 10, 50, 100, 200, and 500  $\mu\text{g/g}$ . After mixing, glass beakers containing 20 mL of 0.2–0.5-N KOH were placed in the bottles for trapping  $CO_2$  evolved from metabolic activity of the bacteria. Further study was initiated to test the capacity of two hydrazine-degrading bacteria, *Achromobacter* sp. and *Pseudomonas* sp., to degrade MMH in the soil [842]. A strain of *Achromobacter* sp. and a strain of *Pseudomonas* sp. that had the capacity to degrade hydrazine in the presence of a second nitrogen source such as ammonium nitrate were used for this study. The bacteria were maintained in a basal mineral medium containing 10  $\mu\text{g/g}$  of MMH or 100  $\mu\text{g/g}$  of hydrazine in culture fluids and cell suspensions. MMH in soil samples was extracted with cold and deoxygenated 0.1M HCl and then determined using a colorimetric method. In addition,  $^{14}\text{C}$  radioisotope-labeled MMH was used for determination of the disappearance of MMH and the formation of metabolites and radioactivity in culture fluids and metabolites was determined by scintillation counting.

A lab study of the batch culture degradation of rocket test site wastewater containing mixtures of MMH, citric acid, and their reaction product showed that the organic contaminants were degraded by *Achromobacter* sp., *Rhodococcus* B30 and *Rhodococcus* J10 [843, 844]. Although the *Achromobacter* sp. showed a preference for the degradation of the citric acid, the *Rhodococcus* sp. were most effective in digesting MMH and MMH citrate. The aerobic biodegradation of wastewater that contained mixtures of highly concentrated MMH/hydrazine/citric acid and their reaction product was studied on a laboratory-scale fixed film trickle-bed reactor [845]. The degrading organisms, *Achromobacter* sp., *Rhodococcus* B30, and *Rhodococcus* J10, were immobilized on coarse sand grains used as support media in the columns. Under continuous recirculating flow conditions, *Rhodococcus* sp. degraded the MMH content of the wastewater from a concentration of 10 to 2.5 mg/mL within 12 days and the hydrazine from ~0.8 to 0.1 mg/mL in 7 days. The *Achromobacter* sp. was equally efficient in degrading the organics present in the wastewater, reducing the concentration of MMH from 10 to

~5 mg/mL within 12 days and that of hydrazine from ~0.8 to 0.2 mg/mL in 7 days. The pseudo first-order rate constants of 0.137 and 0.232 day<sup>-1</sup> were obtained for the removal of MMH and hydrazine respectively in wastewater in the reactor column. In the batch cultures, rate constants for the degradation were 0.046 and 0.079 day<sup>-1</sup> for MMH and hydrazine, respectively. These results demonstrated that the continuous flow bioreactor achieved greater degradation efficiencies than those obtained when the wastewater was incubated with the microbes in growth-limited batch experiments. It was noted that wastewater containing hydrazine was more amenable to microbial degradation than wastewater predominantly containing MMH, in spite of the longer initial lag period observed for hydrazine-containing wastewater. The results of the laboratory scale study were intended to be used in the design and operation of an industrial-size immobilized biofilm reactor for the treatment of MMH- and hydrazine-contaminated wastewater from rocket test sites.

### 13 Fuel Mixtures with MMH

Methylhydrazine has been mixed with other fuels to achieve desirable physical properties (low freezing points), better performance, or improved hypergolic ignition as a fuel. In addition to fuel mixtures that were intended to be used with a hypergolic oxidizer (NTO, inhibited red fuming nitric acid [IRFNA], ClF<sub>3</sub> or ClF<sub>5</sub>), MMH has been the main constituent of monopropellant mixtures such as MHF-5 and MHF-1, where improvement was achieved by adding an MMH-soluble oxidizer such as HN. The compositions of various MMH fuel mixtures are listed in Table 59.

**Table 59:** Composition of mixed hydrazine fuel (MHF) blends containing methylhydrazine.

| Designation         | Composition, mass-%                                                                         |                               |      |                  |
|---------------------|---------------------------------------------------------------------------------------------|-------------------------------|------|------------------|
|                     | MMH                                                                                         | N <sub>2</sub> H <sub>4</sub> | HN   | H <sub>2</sub> O |

<sup>a</sup> From [79]

### 13.1 Mixtures of MMH with Hydrazine

There are numerous binary and ternary fuel mixtures of MMH with hydrazine. Not all of these are worth referencing here in detail, and some are only of historical interest, so the following sections are only a sampling of some of the information that is available. No claim is made here as to the completeness of the chapter on MMH fuel mixtures. Additional data on MMH fuel blends can be found in USAF Propellant Handbook, Hydrazine Fuels [79]. Some of the data listed there were marked only as “provisional data,” which apparently would need confirmation from another source before they can be published. None of those data is repeated here. Physical properties of MMH–hydrazine mixtures were already described in Sections 2.4.1.2 and 2.7.2.

Aerozine-76, Ae-76, was a blend of 76% MMH and 24% hydrazine at one time formulated by Aerojet to contain the same amount of carbon as Aerozine-50 and intended as a replacement for Ae-50. It freezes at  $\sim 237\text{K}$  ( $-33^\circ\text{F}$ ). No additional data could be found.

### 13.2 Mixed Hydrazine Fuel 3

The most thoroughly investigated fuel mixture with MMH is MHF-3, also called M-86, which has been considered as a fuel in combination with many different hypergolic oxidizers. The main advantage of such combinations was their storability at room temperature and hypergolic ignition (to be discussed in a future *Encyclopedia of Hypergolic Bipropellant Combinations*, chapter “Hypergolic Combinations with Nitrogen Oxides”). In addition to its use as a fuel, MHF-3 has also been used as a monopropellant and actually has flown as a gas generant for emergency power supplies on early versions of the French/British Supersonic Transport SST CONCORDE.

#### 13.2.1 Physical Properties of MHF-3

The USAF Propellant Handbooks, Hydrazine Fuels, Vol. 1. contains a unit (Unit 2.7) with physical properties of MHF-3 from which the following were copied [846]. It also contains numerous graphs depicting the physical properties of MHF-3 as a function of temperature, both in SI and American engineering units.

##### 13.2.1.1 Density of MHF-3

The density of MHF-3 from 219 to 367 K ( $-54$  to  $+94^\circ\text{C}$ ) can be expressed as a linear function of temperature

$$\rho = 1.1716 - 9.4836 \times 10^{-4} T$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $T$  is the temperature in kelvin. The density of MHF-3 is illustrated in Figure 44.

**Figure 44:** Density of MHF-3. (Reproduced and modified from [79].)

### 13.2.1.2 Velocity of Sound and Compressibility of MHF-3

The velocity of sound in MHF-3 as a function of temperature can be represented by the linear equation:

$$c = 2808.5 - 4.0427T$$

where  $c$  is the velocity of sound in m/s and  $T$  is the temperature in kelvin. The adiabatic compressibility of MHF-3 can be derived from the sonic velocity and density and is represented by the following polynomial equation:

$$\beta_a = 1.6201 \times 10^{-4} + 1.9278 \times 10^{-6}T - 6.8281 \times 10^{-9}T^2 + 8.9935 \times 10^{-12}T^3$$

where  $\beta_a$  is the adiabatic compressibility in  $\text{atm}^{-1}$  and  $T$  is the temperature in kelvin.

### 13.2.1.3 Vapor Pressure of MHF-3

The vapor pressure of MHF-3 is dominated by the vapor pressure of its more volatile, more prevalent component, MMH. The vapor pressure of MHF-3 within the range from 273 to 363 K (0 to 90 °C) can be calculated from the equation:

$$\log P = 8.2748 - (1956.91/T)$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. The vapor pressure of MHF-3 is illustrated in Figure 45.

**Figure 45:** Vapor pressure of MHF-3.  
(Reproduced and modified from [79].)

### 13.2.1.4 Viscosity of MHF-3

The absolute viscosity of liquid MHF-3 can be calculated from the equation:

$$\log \mu = -11.179 + \frac{9291.8}{T} - \frac{2.7687 \times 10^6}{T^2} + \frac{2.9336 \times 10^8}{T^3}$$

where  $\mu$  is the absolute viscosity in cPs and  $T$  is the temperature in kelvin. The absolute viscosity of MHF-3 is illustrated in Figure 46.

### 13.2.1.5 Surface Tension of MHF-3

The surface tension of MHF-3 within the range from 229 to 367 K (−44 to 94 °C) can be calculated from the equation:

$$\sigma = 37.4305 + 0.09252 T - 3.2915 \times 10^{-4} T^2$$

where  $\sigma$  is the surface tension in dyn/cm and  $T$  is the temperature in kelvin. To convert from dyn/cm to N/cm, divide by  $10^5$ . The surface tension of MHF-3 is illustrated in Figure 47.

**Figure 46:** Absolute viscosity of liquid MHF-3. (Reproduced and modified from [79])

**Figure 47:** Surface tension of MHF-3. (Reproduced and modified from [79])

### 13.2.1.6 Thermal Conductivity of MHF-3

The thermal conductivity of MHF-3 within the range from 255 to 395 K (–18 to 122°C) can be calculated from the equation:

$$\lambda = 7.3524 \times 10^{-4} + 5.0303 \times 10^{-7} T - 2.5343 \times 10^{-9} T^2$$

where  $\lambda$  is the thermal conductivity in  $\text{cal cm}^{-1} \text{s}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin. To convert from  $\text{cal cm}^{-1} \text{s}^{-1} \text{°C}^{-1}$  to  $\text{W m}^{-1} \text{K}^{-1}$ , multiply by 418.4. The thermal conductivity of liquid MHF-3 is illustrated in Figure 48.

**Figure 48:** Thermal conductivity of liquid MHF-3. (Reproduced and modified from [79].)

### 13.2.2 Chemical Properties of MHF-3

The chemical composition of MHF-3 is defined by Military Specification MIL-P-81342(WP) – Propellant, Mixed Hydrazine Fuel, MHF-3 [847] as listed in Table 60.

#### 13.2.2.1 Analysis of MHF-3

Analytical methods to be used for quality control and acceptance tests of MHF-3 are specified in MIL-P-81342(WP).

**Table 60:** Specification requirements for MHF-3 as per MIL-P-81342(WP).

| Constituents                                | Composition, mass-%                                          | Specification requirements               |
|---------------------------------------------|--------------------------------------------------------------|------------------------------------------|
| Methylhydrazine                             | $86.0 \pm 2.0$                                               | MIL-P-27404                              |
| Hydrazine                                   | $14.0 \pm 2.0$                                               | MIL-P-26536                              |
| Water, plus soluble impurities <sup>a</sup> | 2.0 maximum                                                  | —                                        |
| Particulate                                 | 10 mg/L                                                      | —                                        |
| Density                                     | $0.892\text{--}0.896\text{ g/cm}^3$ at 298 K (25 °C = 77 °F) | Method 402.2 of FED-STD-791 (ASTM-D941). |
| Freezing point                              | $<219.26\text{ K} = -54.4\text{ °C} = -65\text{ °F}$         | ASTM-D1177                               |

<sup>a</sup> Water content shall be 1 mass-% maximum if fuel is to be used for metallized slurry fuels

### 13.2.2.2 Gas Chromatographic Methods for Analysis of MMH Mixtures

The MMH/N<sub>2</sub>H<sub>4</sub>/H<sub>2</sub>O assay per MIL-P-81342(WP) can be done by GC at 373 K (100 °C). The recommended column filling was 30% Quadrol (*N,N,N',N'*-tetrakis-3-hydroxypropyl ethylenediamine) on 30–50 mesh firebrick in a column measuring ¼ in. diameter × 5 ft, a kind of antique method. Modern gas chromatographs using Chromosorb or capillary columns easily separate the three ingredients. Amine impurities may include methylamine, which elutes first.

Improved separation of all three hydrazines and water was achieved by using a stationary phase that is chemically similar to hydrazine [848]. In this case, 2-hydrazinopyridine, a polar liquid of low volatility, was used as the stationary phase in 10% concentration on Fluoropak 80. A synthetic blend consisting of 27.9% N<sub>2</sub>H<sub>4</sub>, 27.9% MMH, 22.2% UDMH, and 21.9% H<sub>2</sub>O was analyzed in replicate ten times, and mean errors (uncorrected for response factors) ranged from –0.4 (UDMH) and –0.3 (MMH) to +0.8% (N<sub>2</sub>H<sub>4</sub>) absolute. The constituents elute in the sequence UDMH, H<sub>2</sub>O, MMH, and N<sub>2</sub>H<sub>4</sub>.

The GC method recommended by Olin for the analysis of hydrazine/MMH mixtures such as MHF-3 used a ¼-in. × 6-ft stainless-steel column packed with 30–60 mesh with 15% triethanolamine on Chromosorb W. Recommended column temperature is 378 K. A response factor of 0.978 is used for hydrazine and 1.152 for MMH when calculating the results. The water response factor must be determined from case to case by analyzing a mixture with a known content of water. Gas chromatographic separation of hydrazine and MMH in combination with a wet chemistry method for total hydrazines eliminated the need to change columns when water must be expected in N<sub>2</sub>H<sub>4</sub>/MMH mixtures [849]. A ¼ × 12-in. copper (!) column packed with 23% Carbowax 1500 on Johns-Manville C-22 firebrick, isothermal at 363 K, was used for N<sub>2</sub>H<sub>4</sub>/MMH separation. Copper as tubing material for the column is *not* a good choice when working with hydrazines. Total hydrazines were then titrated with 0.1 M KIO<sub>3</sub>. The difference was assumed to be water.

Another GC method for the analysis of MMH fuel blends used a column packed with 10% Dowfax 9N9 on Teflon 6 [360]. The peaks appeared in the order of water, MMH, and hydrazine. The composition analyses were duplicated within  $\pm 0.5\%$  of the amount of the individual components present in a synthetic mixture. Nowadays, nobody still uses packed columns and much better separation can be achieved with capillary columns.

Hydrazine/MMH and hydrazine/UDMH mixtures can be analyzed by reactive column GC [383]. Linearity of methane production with sample size could be demonstrated if decomposition occurred on a copper oxide catalyst heated to 573 K. The hydrazine/MMH mixtures gave linear methane peak area response at between 20 and 80% MMH, but the practically more important 86% MMH mixture was not run, leaving some questions as to the suitability of this method for MHF-3 analysis. In repetitive analysis of 50:50  $\text{N}_2\text{H}_4$ /MMH mixtures, a coefficient of variation of 1.7% (for MMH) was obtained, corresponding to a standard deviation of  $\pm 0.9\%$  relative.

In another reactive GC method, nitrogen content of hydrazine mixtures was determined in an apparatus coupled with the GC using chromic acid or bromide–bromate solution as an oxidant [850]. Gaseous products were collected in a bulb, which was part of the by-pass injector. At the end of the reaction the products were determined chromatographically.

#### 13.2.2.3 Titrimetric Methods for Analysis of MMH Mixtures

Mixtures of hydrazine and MMH were determined by an oxidation-aldehyde method based on the selective reaction of  $\text{N}_2\text{H}_4$  with salicylaldehyde and subsequent titration of MMH with potassium iodate. Two aliquots were used, (a) for determining total hydrazines, (b) for determining MMH, by titration with potassium iodate. The  $\text{N}_2\text{H}_4$ , precipitated as salicylidine azine, was determined by difference. It was attempted to extend Malone's method using salicylaldehyde in the presence of excess perchloric acid to determine admixtures of  $\text{N}_2\text{H}_4$  and MMH [401]. The excess perchloric acid was back-titrated with sodium acetate. This non-aqueous acid–base method was simple and effective but required the use of two standard titrants.

#### 13.2.3 Materials Compatibility for MHF-3 Equipment

Mixed hydrazine fuels contain mostly MMH in a mixture with either hydrazine–HN or hydrazine by itself (MHF-3). Maraging steels are preferred for pressure tanks, but the rate of pressure buildup with MHF-3 was prohibitive. It has been attempted to retard the decomposition of MHF-3 by electroplating or electroless plating steel tanks internally with nickel [851–855]. Some coatings other than nickel, for instance, cadmium, would also reduce the rate of gas evolution. The ability of cadmium to reduce the catalytic activity of maraging steels makes it a preferred coating, but cadmium is gradually corroded by MHF-3, making it a sacrificial coating. Electroless

nickel from a hypophosphite bath was more durable and easier to apply to the interior of tanks. Unprotected maraging steels, AM-355 and Inco-718, were not compatible with MHF-3. Although the EPU on the CONCORDE SST was flown only for a short period, a description of transportation regulations for fueled EPUs continues to exist in 49CFR § 173.172. It describes tanks having either a welded aluminum bladder or an elastomeric bladder with a maximum internal volume of 46 L (12 gal). The outer vessel must have a minimum design gauge pressure of 1275 kPa (185 psi) and a minimum burst gauge pressure of 2755 kPa (400 psi). The nesting bellows tank used to hold 28.6 kg (63 lb) of M-86 propellant on board the CONCORDE SST EPU was manufactured by Metal Bellows Corporation. It had an expulsion efficiency of 83% and had demonstrated 140 full expulsion cycles, more than was ever needed for ordinary EPU applications.

An all-glass apparatus with an attached all-glass Bourdon tube called a “Staco” cell was used to measure gas evolution of MHF-3 in contact with a number of metals at 347 K [856]. A mirror was mounted on the tip of the Bourdon tube, and the tube deflection could be read with a beam of light reflected from the mirror. Each tube had to be individually calibrated while dry, as no two thin-walled glass Bourdon tubes were alike. The compatibility of various pure metals with MHF-3 was determined at 347 K (74 °C = 165 °F). Metals investigated included titanium, copper, iron, aluminum, and nickel under the annealed and cold-worked conditions, and chemically deposited chromium. Tests were conducted in an all-Pyrex, torch-sealed pressure vessel. Pressure changes were recorded over a 94-day period. The worst pressure rise, 0.6 and 0.2 psi/day, was with annealed and cold-worked iron or copper. Post-exposure evaluations of the metals were made by electron microscopic examination, microprobe analysis, and tensile tests. Each specimen was weighed before and after the 94-day immersion in MHF-3. All specimens underwent a small loss in weight. The weight losses of the various metals did not correlate with the degree of propellant decomposition. For instance, titanium caused no pressure increase in the cell, yet its weight change, compared with other metals, was relatively high. The greatest variation in physical tensile strength properties due to MHF-3 exposure was found in the cold-worked aluminum. All the other metals tested showed no property changes greater than the expected variation of testing. Cold-worked Al and Ti samples gradually annealed themselves during the 347 K exposure. Table 61 gives a summary of hydrazine blends materials compatibility tests.

Compatibility of MHF-3 in comparison with hydrazine, MHF-5, MGGP-1, MGGP-3, and BAF-1185 was tested in pressure vessels made from Al-1100-0, Al-2014-T6, Al-6061-T6, CRES-347 steel or Inconel 718 for 1 year at 347 K (165 °F) [857]. The lowest pressure rise was in the aluminum alloys and the highest pressure rise was in CRES-347, accompanied by propellant discoloration to dark amber and reddish brown.

**Table 61:** Literature references to mixed hydrazine fuel (MHF) materials compatibility tests.

| Blend designation | Materials tested                              | Type of tests                                                                               | References |
|-------------------|-----------------------------------------------|---------------------------------------------------------------------------------------------|------------|
| MHF-3             | Al-1100-00, Al-2014-T6, CRES-347, Inconel-718 | Tank storage, pressure rise, fuel analysis, weld samples                                    | [857]      |

#### 13.2.4 Toxicity of MHF-3

The toxicity of MHF-3 is determined by its most volatile and most prevalent constituent, MMH.

#### 13.2.5 Safety Properties of MHF-3: Flash Point of MHF-3 in Air

Mixed hydrazine fuel MHF-3 has a flash point of 297 K (24 °C) in air. The spontaneous ignition hazards of MHF-3 (M86) were measured in air and at low pressures [860]. The hazard is very similar to that of MMH itself. Spill decontamination methods were developed for MMH-based propellant mixtures such as MHF-3 or MHF-5 [861].

### 13.3 Mixed Hydrazine Fuel 5

Another thoroughly investigated monopropellant mixture with MMH is MHF-5. MHF-5 is a ternary mixture of MMH, hydrazine, and HN. Hydrazinium nitrate was added to the MMH/hydrazine mixture to avoid formation of soot and to increase its performance as a monopropellant. There are also two variants of this propellant mixture, designated as MHF-5A and MHF-5B. MHF-5 was originally intended for the CONDOR ship-borne missile program and the freezing point was thought to be 202 K (–71 °F), but that was due to supercooling and later investigations showed that the freezing point was actu-

ally 230 K (−43 °F). An interim candidate was MHF-5A, which was formulated to meet a 208 K (−65 °F) freezing point requirement, but it was superseded by MHF-5B after the freezing point requirements were relaxed and a freezing point of 230.4 K (−45 °F) was considered acceptable. All three versions of MHF-5 contain the same amount of HN, 19% HN by mass. The main difference in the three formulations is the amount of MMH. MHF-5B was used for development tests of the CONDOR missile, but the missile was never put into service on any US Navy ship or jet airplane. A solid-propellant air-to-ground missile developed for the Navy in a parallel program, AGM-53, also under the same name CONDOR, did not advance to deployment either.

The gross formula of MHF-5B would be  $C_{0.5784}H_{5.2486}N_{2.0918}O_{0.2755}$ , or, normalized to  $C=1$  where the factor is  $1/0.5784=1.7289$ , the gross formula would be  $C_1H_{9.074}N_{3.616}O_{0.476}$ , indicating that this formula is still under-oxidized for the complete conversion of all carbon to CO.

### 13.3.1 Physical Properties of MHF-5

The USAF Propellant Handbooks, Hydrazine Fuels, Vol. 1, contains two similar units (Unit 2.17 and Unit 2.18) with physical properties of MHF-5 and MHF-5B from which the following properties were copied [862]. It also contains numerous graphs depicting the physical properties of MHF-5 and MHF-5B as a function of temperature, both in SI and American engineering units. MHF-3 has flown whereas MHF-5 has not. Therefore, unlike the format of the MHF-3 section, none of the many graphs from that collection was reproduced here in order to conserve space. Instead, several mathematical equations were given, which allow the user to calculate properties as a function of temperature.

Physical properties of MHF-5 are summarized in Table 62. The physical properties of MHF-5 and MHF-5B are very similar. The following section contains a mix of MHF-5 and MHF-5B properties.

#### 13.3.1.1 Density of MHF-5B

The density of MHF-5B within the range 215 to 344 K (−58 to +71 °C) can be calculated from:

$$\rho = 1.2492 - 8.2274 \times 10^{-4} T$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin. There is also an equation that allows us to calculate the density of MMH/ $\text{N}_2\text{H}_4$ /HN mixtures as a function of chemical composition and temperature:

$$\rho = 1.2490 - 7.948 \times 10^{-4} - 5.199 \times 10^{-8} T^2 - 1.512 \times 10^{-3} M + 4.42 \times 10^{-3} N$$

where  $\rho$  is the density in  $\text{g/cm}^3$ ,  $T$  is the temperature in kelvin,  $M$  is the mass-% MMH, and  $N$  is the mass-% HN.

**Table 62:** Physical properties of MHF-5, MHF-5A, and MHF-5B.

| Property                              | SI units                             | Other units                                                                    |                                                              |
|---------------------------------------|--------------------------------------|--------------------------------------------------------------------------------|--------------------------------------------------------------|
| Freezing point                        | 231 K                                | ~-42 °C                                                                        | ~-43 °F                                                      |

<sup>a</sup> Data for MHF-5B

Data source: [110]

**13.3.1.2 Vapor Pressure of MHF-5**

The vapor pressure of MHF-5 within the range 273 to 368 K (0 to 95 °C) can be calculated from

$$\log P = -61.243 + 5725.80/T + 0.20818 T - 2.0727 \times 10^{-4} T^2$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin.

**13.3.1.3 Viscosity of MHF-5B**

The absolute viscosity of MHF-5B within the range 233 to 366 K (-40 to 93.3 °C) can be calculated from the equation:

$$\log \mu = -3.9625 + \frac{3087.4}{T} - \frac{9.7161 \times 10^5}{T^2} + \frac{1.2820 \times 10^8}{T^3}$$

where  $\mu$  is the absolute viscosity in cPs and  $T$  is the temperature in kelvin.

**13.3.1.4 Thermal Conductivity of MHF-5**

The thermal conductivity of liquid MHF-5 consisting of 55% MMH, 26% N<sub>2</sub>H<sub>4</sub>, and 19% HN, was reported (at 298 K) as  $7.5 \times 10^{-4}$  cal cm<sup>-1</sup> s<sup>-1</sup> K<sup>-1</sup> (0.1819 BTU h<sup>-1</sup> ft<sup>-1</sup> °F<sup>-1</sup>) [110]. The thermal conductivity of MHF-5 can be calculated from:

$$\lambda = 9.4074 \times 10^{-4} - 6.3264 \times 10^{-7} T$$

where  $\lambda$  is the thermal conductivity in cal cm<sup>-1</sup> s<sup>-1</sup> °C<sup>-1</sup> and  $T$  is the temperature in kelvin. To convert from cal cm<sup>-1</sup> s<sup>-1</sup> °C<sup>-1</sup> to W m<sup>-1</sup> K<sup>-1</sup>, multiply by 418.4.

### 13.3.2 Chemical Properties of MHF-5

The chemical composition of MHF-5 is defined by Military Specification MIL-P-81507 – Propellant, Mixed Hydrazine Fuel, MHF-5, as listed in Table 63. MHF-5 formulations lack thermal stability [863].

**Table 63:** Specification requirements for MHF-5 as per MIL-P-81507.

| Constituents                   | Composition, mass-%                 | Specification requirements               |
|--------------------------------|-------------------------------------|------------------------------------------|
| Methylhydrazine                | $55.0 \pm 2.0$                      | MIL-P-27404                              |
| Hydrazine                      | $26.0 \pm 2.0$                      | MIL-P-26536                              |
| Hydrazinium nitrate            | $19.0 \pm 2.0$                      | —                                        |
| Water, plus soluble impurities | $\leq 2.0$                          | —                                        |
| Particulate                    | 10.0 mg/L                           | —                                        |
| Density at 298 K               | 1.00 to 1.02 g/cm <sup>3</sup>      | Method 402.2 of FED-STD-791 (ASTM-D941). |
| Freezing point                 | $202.1 \pm 2.8$ K ( $-71 \pm 5$ °F) | ASTM-D1177                               |

### 13.3.3 Materials Compatibility of MHF-5 and MHF-5B

Pressure rise was measured during long-term storage tests with MHF-5 in CRES-321 tanks with 2% ullage, and the pressure rise was very fast, 1.27 MPa (185 psi) in 8 months. In Al-2219, the pressure rise was only 34 kPa (5 psi) when stored at ambient temperature and 860 kPa (125 psi) when stored at 328 K [110].

### 13.3.4 Equipment for Handling of MHF-5 and MHF-5B

As part of the long-term storage program at AFRPL, General Dynamics supplied 23 tanks filled with MHF-5, NTO, or ClF<sub>5</sub> [864]. The tanks contained either surface tension screen PMDs or rolling metal diaphragm positive expulsion devices and were connected to three different types of expulsion pressurization devices: solid propellant gas generators, liquid propellant gas generators, or compressed gas bottles. These assemblies were stored for up to 10 years.

Propellant tanks for MHF-5 long-term storage tests need to be carefully cleaned and passivated before filling them with MHF-5 [865]. For comparison, storage of MHF-5 in metal tanks is much more difficult than that of MHF-3 because it is more corrosive [595, 858, 859].

### 13.3.5 Safety Properties of MHF-5 and MHF-5B

#### 13.3.5.1 Drop Weight Sensitivity of MHF-5 and MHF-5B

If MHF-5, MHF-5B, or MHF-1 freeze slowly, HN precipitates and accumulates at the bottom, constituting an increased safety hazard. Even after the mixture thaws and it is not stirred soon after to re-mix it, its bottom layer may be more sensitive to shock.

**Figure 49:** Drop weight impact sensitivity of methylhydrazine/ $\text{N}_2\text{H}_4$ /hydrazinium nitrate mixtures. (Reproduced and modified from [79].)

Mixtures would then be in the apex area of the triangular chart in Figure 49, an area one would always try to avoid. Mixtures containing >35% HN are shock sensitive. The mass of the impactor and the drop height were not specified in the source of this graph. It is assumed that the impactor mass was 2 kg.

#### 13.3.5.2 Card Gap Sensitivity of MHF-5 and MHF-5B

A graph showing the card gap sensitivities of ternary MMH/ $\text{N}_2\text{H}_4$ /HN mixtures including MHF-5 and MHF-5B is shown in Figure 50. As can be seen in this graph, mixtures with 30–40% HN are detonable even with a 25-cm (10 in) gap. MHF-1 is very close to the boundary of detonability, but still on the safe side.

### 13.4 Mixed Hydrazine Fuel 1

Another thoroughly investigated monopropellant mixture with MMH is MHF-1, which has been considered as a monopropellant and hypergolic fuel with RFNA, NTO, or  $\text{ClF}_3$ . Data points for MHF-1 properties were already shown in several of the MMH/ $\text{N}_2\text{H}_4$ /HN ternary mixture property charts, in comparison with the properties of MHF-5.

#### 13.4.1 Physical Properties of MHF-1

The USAF Propellant Handbooks, Hydrazine Fuels, Vol. 1, contains a unit (Unit 14) with physical properties of MHF-1 from which the following properties were copied

**Figure 50:** Card gap sensitivity of methylhydrazine/ $\text{N}_2\text{H}_4$ /hydrazinium nitrate mixtures. (Reproduced and modified from [79].)

[866]. It also contains numerous graphs depicting the physical properties of MHF-1 as a function of temperature, both in SI and American engineering units, but we could not reproduce all of those here owing to a lack of space. It is unlikely that MHF-1 will be used again, so the data are only of historical interest.

Mixed hydrazine fuel-1 was dropped from consideration because of its high rate of pressure buildup during hermetic storage tests and also because of its high viscosity and its tendency to explode in open-cup burning tests where the volatile fuels burn first and the HN-enriched residue explodes.

#### 13.4.2 Chemical Properties of MHF-1

The chemical composition of MHF-1 is 45.3% MMH, 31.4%  $\text{N}_2\text{H}_5\text{NO}_3$ , and 23.3%  $\text{N}_2\text{H}_4$ . With such a high HN content, this formulation is borderline to detonability and shock sensitivity limits shown in some of the previous triangular charts. The gross formula of MHF-1 is  $\text{C}_{0.48183}\text{H}_{5.12553}\text{N}_{2.16187}\text{O}_{0.48562}$ , or, normalized to  $\text{C} = 1$ , the gross formula would be  $\text{C}_1\text{H}_{10.637}\text{N}_{4.4868}\text{O}_{1.008}$ , which shows that this mixture contains more than sufficient oxygen to burn all carbon to CO and thus it should have a very clean, soot-free exhaust when it is used as a monopropellant.

#### 13.4.3 Toxicity of MHF-1

The acute toxicity of MHF-1, a mixture of 45.3% MMH, 23.3%  $\text{N}_2\text{H}_4$ , and 31.4% HN, is essentially identical to that of MMH [867].

### 13.5 Ternary Fuel Mixtures of MMH with Hydrazine and Water

Adding water to MMH/hydrazine fuel mixtures would decrease the performance as a fuel, but would also lower the freezing point. There are three fuel blends with these three constituents that have been characterized, but no flight applications are known. The compositions of these three mixtures have already been shown in Table 59.

#### 13.5.1 Mixed Hydrazine Fuel 6

Another thoroughly investigated monopropellant mixture with MMH is MHF-6, which has been considered a low-freezing point fuel, although adding water would lower the performance compared with MHF-3. MHF-6 consists of 73.0% MMH, 18.5%  $\text{N}_2\text{H}_4$ , and 10.5%  $\text{H}_2\text{O}$ . This composition can also be written as 73% MMH and 27% hydrazine hydrate  $\text{N}_2\text{H}_5\text{OH}$ . It is roughly midway between MHF-3 and BAF-1185 in composition and many of its properties are similar to those of the latter two fuels.

The advantage of MHF-6 over MHF-3 or MHF-1 is that it can be prepared from hydrazine hydrate, hydrazine, and MMH instead of anhydrous hydrazine and MMH. MHF-6 would be a better regenerative coolant, result in lower flame temperatures, at the expense of lower specific impulse. The empirical formula for MHF-6 is  $\text{C}_{1.58437}\text{H}_{12.73128}\text{N}_{4.19845}\text{O}_{0.582815}$ .

#### 13.5.2 Physical Properties of MHF-6

The USAF Propellant Handbooks, Hydrazine Fuels, Vol. 1, contains a unit (Unit 2.19) with physical properties of MHF-6 from which the following properties were copied [868]. It also contains numerous graphs depicting the physical properties of MHF-6 as a function of temperature, both in SI and American engineering units. The freezing point of MHF-6 was marked on Figure 25 as 219.3 K ( $-53.9^\circ\text{C}$ ).

##### 13.5.2.1 Density of MHF-6

The density of MHF-6 over the temperature range from 219 to 347 K ( $-54$  to  $+74^\circ\text{C}$ ) can be calculated from the equation:

$$\rho = 1.1951 - 9.1500 \times 10^{-4} T$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $T$  is the temperature in kelvin.

##### 13.5.2.2 Vapor Pressure of MHF-6

The vapor pressure of MHF-6 over the range 318 to 366 K ( $45$  to  $93^\circ\text{C}$ ) can be calculated from the equation:

$$\log P = 8.1579 - (1937.63/T)$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin.

### 13.5.3 Chemical Properties of MHF-6

The chemical composition of MHF-6 is defined by Military Specification MIL-P-81726 – Propellant, Mixed Hydrazine Fuel, MHF-6 [869], as listed in Table 64. Apparently, the armed forces must have had an application for MHF-6 in mind because it is one of the few MMH-based fuels that has advanced to the stage of having a MIL-SPEC issued for it.

**Table 64:** Specification requirements for MHF-6 per MIL-P-81726.

| Constituents       | Composition, mass-%                                                                     | Specification requirements               |
|--------------------|-----------------------------------------------------------------------------------------|------------------------------------------|
| Methylhydrazine    | $72.5 \pm 0.5$                                                                          | MIL-P-27404                              |
| Hydrazine          | $17.0 \pm 1.0$                                                                          | MIL-P-26536                              |
| Water, de-ionized  | $10.5 \pm 0.5$                                                                          | —                                        |
| Soluble impurities | 0.5 max.                                                                                | —                                        |
| Particulate        | 10 mg/L maximum                                                                         | —                                        |
| Density            | $0.922 \text{ g/cm}^3$ at $298 \text{ K} = 25^\circ\text{C}$                            | Method 402.2 of FED-STD-791 (ASTM-D941). |
| Freezing point     | $216.5 \pm 1.7 \text{ K} = -56.7^\circ\text{C} = -70^\circ\text{F} \pm 3^\circ\text{F}$ | ASTM-D1177                               |

## 13.6 BAF-1014

BAF-1014 or BA-1014 is a ternary mixture of MMH, hydrazine, and water, similar to MHF-6 and BAF-1185. BAF-1014 consists of 24.0% MMH, 66.7%  $\text{N}_2\text{H}_4$ , and 9.3%  $\text{H}_2\text{O}$ . Properties of BAF-1014 are described in the USAF Propellant Handbook, Hydrazine Fuels. Vol. 1, Unit 2.20 [870]. BAF-1014 and BAF-1185 as fuels with some oxygen in the form of water in their composition were formulated to be used as fuels in combination with fluorine or interhalogens ( $\text{ClF}_3$  or  $\text{ClF}_5$ ) as oxidizers. The oxygen in the fuel was there to combine preferentially with carbon, forming carbon monoxide instead of soot in the exhaust. It is believed that the first two letters in the BAF designation were derived from the name of the company where the fuels were developed, Bell Aerospace.

### 13.6.1 Physical Properties of BAF-1014

The freezing point of BAF-1014 was marked on Figure 25 as  $254 \text{ K}$  ( $-19.2^\circ\text{C}$ ).

### 13.6.2 Density of BAF-1014

The density of BAF-1014 as a function of temperature over the range  $258$  to  $298 \text{ K}$  ( $-15$  to  $+25^\circ\text{C}$ ) can be calculated from the linear equation:

$$\rho = 1.2422 - 8.673 \times 10^{-4} T$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin.

### 13.6.3 Vapor Pressure of BAF-1014

The vapor pressure of BAF-1014 over the range 268 to 365 K (−5 to +92°C) can be calculated from the equation:

$$\log P = 7.7766 - (1862.50/T)$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin.

### 13.7 BAF-1185

BAF-1185 or BA-1185 is a ternary mixture of MMH, hydrazine, and water, similar to MHF-6 and BAF-1014. BAF-1185 consists of 50.5% MMH, 29.8%  $\text{N}_2\text{H}_4$ , and 19.7%  $\text{H}_2\text{O}$ . Properties of BAF-1185 are described in the USAF Propellant Handbook, Hydrazine Fuels. Vol. 1, Unit 2.21 [871]. The freezing point of BAF-1185 was marked on Figure 25 as 219.2 K (−53.9°C). The density of BAF-1185 as a function of temperature over the range 225 to 345 K (−48 to +72.4 °C) can be calculated from the linear equation:

$$\rho = 1.2066 - 8.4742 \times 10^{-4} T$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $T$  is the temperature in kelvin.

### 13.8 Mixtures of MMH with UDMH

The properties of mixtures of MMH with UDMH could be discussed under the heading MMH or UDMH. It was decided to place this section here under MMH.

**Table 65:** Densities and viscosities of the eutectic solution of methylhydrazine–unsymmetrical dimethylhydrazine.

| Temperature |       | Density                | Absolute viscosity | Kinematic viscosity |
|-------------|-------|------------------------|--------------------|---------------------|
| K           | °C    | $\text{g}/\text{cm}^3$ | cPs                | cSt                 |
| 298         | 25.0  | 0.8211                 | 0.617              | 0.751               |
| 283         | 10.0  | 0.8358                 | 0.809              | 0.968               |
| 273         | 0.0   | 0.8454                 | 1.004              | 1.188               |
| 263         | −10.0 | 0.8552                 | 1.299              | 1.519               |
| 253         | −20.0 | 0.8650                 | 1.743              | 2.015               |
| 243         | −30.0 | 0.8747                 | 2.489              | 2.846               |
| 233         | −40.0 | 0.8844                 | 3.866              | 4.371               |
| 223         | −50.0 | 0.8940                 | 6.607              | 7.390               |
| 213         | −60.0 | 0.9033                 | 13.68              | 15.14               |
| 203         | −70.0 | 0.9118                 | 36.06              | 39.55               |
| 200.6       | −72.5 | 0.9160                 | 49.97              | 54.55               |

Data source: [60]

The phase relations of the system MMH/UDMH showed a eutectic freezing at 193 K ( $-80^{\circ}\text{C} = -112^{\circ}\text{F}$ ) at the composition: 39.8 mass-% MMH and 60.2% UDMH. Eutectic mixtures of MMH and UDMH have densities of  $0.9033\text{ g/cm}^3$  at 213 K ( $-60^{\circ}\text{C}$ ) and  $0.9118\text{ g/cm}^3$  at 203 K ( $-70^{\circ}\text{C}$ ). The viscosities of these mixtures are 13.68 cPs at 213 K ( $-60^{\circ}\text{C}$ ) and 36.06 cPs at 203 K ( $-70^{\circ}\text{C}$ ) [60]. See the data in Table 65. There are no known flight uses of MMH/UDMH fuel blends.

### 13.9 Other Fuel Mixtures with MMH

In search of a freezing point suppressant for MMH in bipropellant systems, five different organic additives and water were tested to measure the effects on freezing points, densities, vapor pressures, and to calculate the potential effect on bipropellant performance with NTO as the oxidizer [226]. The additives tested in quantities between 5 and 40% were: urea, acetamide, 1-methyl-1-phenylhydrazine, *N,N*-dimethylformamide, and formamide. Other than water, which would have lowered performance and caused corrosion, *N,N*-dimethylformamide was the best candidate additive for lowering the freezing point without excessive losses of performance. Addition of 5% *N,N*-dimethylformamide lowered the freezing point to below 203 K ( $-70^{\circ}\text{C}$ ), increased the density at 299 K ( $26.5^{\circ}\text{C}$ ) to  $0.875\text{ g/cm}^3$ , and increased the boiling point to 362 K ( $91^{\circ}\text{C}$ ).

Fuel mixtures of MMH with methanol were tested as fuels with RFNA. It was proposed that MMH needs or can use more oxygen during combustion with RFNA. This suggested that MMH could benefit from the addition of an oxygenating agent. Therefore, MMH was “oxygenated” with methanol up to 45 mol-% and reacted with RFNA [872]. The results in Figure 51 show that the density of the mixtures does not follow ideal solution behavior. For methanol concentrations below 23 mass-% the density of the mixture was actually greater than that of pure MMH, as noted by the horizontal line added to Figure 51. The data point in Figure 51 at 32 mass-% methanol does not appear to follow the trend of the other data points in the figure. This inflection point could suggest that two different phenomena are taking place within this system that begin at approximately 23 mass-% methanol and extend to 41 mass-% methanol. It is known that water additions to hydrazine produce hydrates, and similar phenomena may occur in MMH/MeOH.

Mixing MMH and methanol was slightly exothermic. Generally, the mixing of hydrazines with other polar compounds is exothermic. When measuring the heat of mixing for different mixture ratios, a maximum heat of mixing for the MMH/methanol mixtures occurred between 40 and 50 mass-% methanol. Three distinct zones were apparent when graphing the  $\Delta H_{\text{mix}}$  as a function of  $X_{\text{MeOH}}$ . The first was a zone extending to ~20 mass-% methanol (~24 mol-% methanol), this was followed by an inflection point that occurred at the identical concentration to that seen in the volume change on mixing results, and a third zone with near linear  $\Delta H_{\text{mix}}$  data. The maximum with  $-474\text{ J/g} = -0.045\text{ BTU/g}$  was at ~43 mass-% MeOH.

### 13.10 Gelled MMH Fuels

Substantial effort has been devoted over the past decades to gelled MMH fuels, both metallized and without metal additions, but they have yet to find a flight application. Several decades of continued government funding of gelled propellant research have not resulted in a propellant formulation that meets storability requirements of the real world in a battlefield situation.

The promise of gelled fuels was that they would be less susceptible to leakage, even if one or both tanks were hit by shrapnel in a battlefield situation. The shrapnel would still render the one missile unusable, but at least the punctured tank would not start a fire and affect other, still operational missiles in the launch canisters or in the magazine by fratricide.

Gelled propellants are non-Newtonian fluids and therefore exhibit a non-linear relationship between the stress and deformation rate. Depending on the gelling agent used, gelled propellants may also have a finite yield stress. Stresses applied to the fluid below the yield stress do not cause the fluid to flow, but they deform like a solid. Numerous rheological models for non-Newtonian fluid mechanics exist and the choice of rheological model for a particular fluid depends on how well they match experimental data.

A difficulty in preparing gels is the tendency of gelling agents to form lumps as soon as they contact any liquid. The lumps would only slowly disperse and it would take a long time to obtain a uniform gel. Another problem is trapping gas bubbles.

Preparing gels under vacuum with a high-shear mixer may avoid these problems. To avoid the formation of lumps, the hydroxypropyl cellulose (HPC) powder is added slowly in steps of 1%, followed by an intensive period of stirring.

One aspect of the long-term storability of gelled propellants that has often been overlooked is syneresis. Syneresis is the segregation of the gelled propellant into a gelled phase and a liquid phase. Typically, this happens if the tank has an ullage space and the MMH can vaporize from the surface of the gel if temperature differentials exist between the liquid and the ullage. The other mechanism for gel segregation is just the aging of the gel structure, similar to the hardening of polymers with age.

There are only a few open literature papers describing the rheological properties of gelled MMH. Most of those also discuss the gelling of oxidizers to be paired with the gelled MMH in hypergolic bipropellant propulsion systems, usually for tactical missiles.

The rheological properties depend on how fast or how slow a viscosity measurement is performed (shear rate) and the shear history of the fluid. Thixotropy is a time-dependent fluid property where the fluid viscosity decreases with time when shear is applied. Time-dependent fluids retain information of their shear history in the gel microstructure.

A review of the status of gelled MMH and IRFNA system technologies described three types of IRFNA/MMH gels that had been developed for tactical missile applications [873]. The three types are: high performance aluminum-loaded gels, medium performance carbon-loaded gels, and lower performance unloaded gels. Each gel suits a particular application best as the smoke plume visibility increases with increasing performance. For a battlefield situation, a low signature, no-smoke exhaust would be preferred.

Measurements of viscosity hydroxypropyl cellulose shear rate curves for various gel propellants including 2 to 4 mass-% hydroxypropyl cellulose/MMH and 3 to 5 mass-% silica/IRFNA gels were plotted over a range of viscosity measurements on a common plot, although no distinctions were made between different gellant concentrations and the viscosity variation for a single gellant concentration [874]. Thixotropy and yield stress measurements were performed to further classify the behavior of the gel propellants. Hydrazine-based fuels, gelled with polysaccharides, were characterized as shear-thinning pseudoplastic fluids with low shear yield stress. Creep tests were conducted on two rheological types of gels with different gellant content and the results were fitted by a viscoelastic constitutive model. The effect of temperature on the rheological properties of gel propellant simulants was also investigated. A general rheological classification of gel propellants and simulants was proposed.

It is assumed that the same gelling agents that were proven to work for MMH would also work for gelling UDMH, but there has been less interest in gelled UDMH

than gelled MMH. See also [875, 876]. Hydroxypropyl cellulose or fumed silica or a combination of the two can be used for gelling MMH [877, 878].

### 13.10.1 Selection of Gelling Agents

A wide range of organic gelling agents has been tested with MMH, similar to efforts with gelled hydrazine or kerosene [879]. KLUCEL<sup>®</sup> HPC, is a non-ionic water-soluble cellulose ether, which has been used as a gelling agent for MMH. In non-rocket applications, HPC is mainly used as a thickener for adhesives, paint removers, and food, as well as a binder in the chemical and pharmaceutical industries. Cellulose-based derivatives such as HPC, hydroxyethyl cellulose (HEC) and hydroxyalkyl cellulose have been used successfully to gel MMH. Gels with KLUCEL<sup>®</sup> showed little or no thixotropic behavior in comparison with highly thixotropic gels featuring an inorganic gelling agent such as SiO<sub>2</sub> [880]. The viscosity was reduced when shear was applied to the gel; however, the viscosity returned to the original value when the shear stress was removed. Rheological measurements of gelled MMH were performed using a rotational rheometer, applying shear rates up to 1000 s<sup>-1</sup>. The MMH/HPC gel showed a Newtonian plateau for low shear rates where the applied shear rate had no considerable influence on the gel viscosity. For higher shear rates a reduction in viscosity could be observed. The viscosity reduction with increasing shear was less in comparison with silica gels. For shear rates higher than approximately 0.1 s<sup>-1</sup> the MMH gel had a higher viscosity than kerosene gels with the same amount of gelling agent.

In continuation of earlier studies [880], HPC, a polysaccharide, was evaluated as a gelling agent for MMH and the viscosity of the unloaded gels was measured under different shear conditions [877]. In solutions, the polysaccharide chains expand and uncoil, resulting in the formation of an entangled network and an increase in the solution viscosity. Gelled MMH samples were prepared that contained both HPC and fumed silica. The viscosity–shear rate relationship of the MMH and RFNA gels was investigated over a shear rate range from 0.001 to 1000 s<sup>-1</sup>. HPC-based MMH gels were not thixotropic. There were no changes in viscosity after 1-month storage, but such a short storage time is meaningless in view of military storability requirements. The time-independent nature of HPC-based gels made it possible to measure a single sample multiple times without altering the rheology. However, this measurement was not possible because the MMH gels changed (owing to oxidation and CO<sub>2</sub> absorption) in open air, altering the rheology within 10 min of the start of the air exposure. Another gelling agent for alkylhydrazines is polyacrylamide [881].

Methylhydrazine gels with gelling agents consisting of hydroxypropyl methyl cellulose containing 19 to 24 mass-% methoxy groups and 4 to 12 mass-% propoxy groups, dihydroxyethyl cellulose or HPC containing about 4.6 propoxy groups per glucose unit have been patented [882].

Hydroxyethyl cellulose has been frequently used to gel hydrazine and/or alkylhydrazines [883]. MHF-3 and hydrazine were gelled with a combination of 5% cellulose acetate and 1% HEC [884]. MHF-3 and hydrazine were gelled with a combination of 1.5% HEC and 6% colloidal silica [885].

Quaternary alkylammonium salts of polyacrylic acid (Carbopol-940) are effective gelling agents for hydrazine and hydrazine/alkylhydrazine mixtures [886]. See also [887, 888].

### 13.10.2 Metallized Gelled MMH Fuels

A metallized gelled MMH fuel can be made of MMH, 1–3% HPC, metallic fuel particles, and 0.05–0.3% dimethylurea [889, 890]. The metallic fuel particles can be aluminum, magnesium, boron, beryllium, zirconium, aluminum hydride, magnesium hydride, beryllium hydride, or zirconium hydride.

The most thoroughly examined metallized gelled MMH fuel was MICOM Gel, which consisted of 60% aluminum, 38% MMH, and 2% gellant/stabilizer [891]. MICOM Gel had a density of  $1.49 \text{ g/cm}^3$  at 298 K, suffered no settling after 30 min at 500 g acceleration in a centrifuge and in the DSC it may exotherm at 466 K (380 °F).

During the 1960s and 1970s, considerable effort was devoted to developing storable, gelled, hydrazine-based fuels containing various concentrations of aluminum powder. As general interest in these fuels subsided, the one factor that remained to be demonstrated was the storability of gelled fuels for periods of time exceeding 10 years.

Using nano-aluminum made by an exploding wire arc in vacuum (like ALEX) instead of micron-size aluminum powder was expected to produce better metallized gels in MMH or UDMH [892]. The gelling agent was still the same one claimed in earlier patents, HPC with dimethylurea. Numerous static test firings have been conducted with metallized MMH fuels and hypergolic oxidizers, but none of these combinations has found any flight application.

One of the potential benefits of gelled liquid fuels is that gelled liquid fuel propulsion systems in missiles meet Insensitive Munitions (IM-LOVA) safety criteria, whereas many of the solid propellant missiles currently in service do not. For example, an AQM-37A target drone rocket propulsion systems loaded with gelled bipropellants successfully passed the bullet impact, fast cookoff, and slow cookoff IM test requirements of MIL-STD 2105A. Extensive safety testing, in particular cookoff behavior, has been done with gelled propellant propulsion systems. There are many gelled propellant hazard evaluation reports, but in spite of all the widely publicized and favorable test data, gelled systems have not yet been deployed in the field.

### 13.10.3 Carbon-Loaded Gelled MMH Fuels

The disadvantage of metal-loaded MMH gels is the formation of metal oxides in the exhaust that leave a highly visible contrail wherever a missile propelled by such fuels is traveling. In a battlefield situation, that gives away the location of the launch site. A potential additive and gelling agent to MMH is finely divided carbon. Carbon suspensions would increase the density, density-specific impulse, and viscosity of loaded MMH gels, without leaving a tell-tale trace in the exhaust, because CO<sub>2</sub> and CO remain invisible.

Despite the availability of viscosity data, knowledge of the viscosity of a gel such as carbon-gelled MMH is not sufficient to predict the pressure drop across an injector in a rocket engine. The discharge coefficient is assumed and hardware must be fabricated and tested to verify the validity of the assumed discharge coefficient. The propellant formulator does not know the impact on the injector design when the viscosity profiles of gel fuels and oxidizers are altered. Without information about the impact of viscosity on the injector design, one cannot distinguish between hardware design problems and propellant formulation problems.

### 13.10.4 Gelled MHF-3 Fuels

MHF-3 can be gelled with the same gelling agents that also have been shown to work with MMH. Gelling agents proposed for MHF-3 include ethyl cellulose or colloidal silica [885], or fumed SiO<sub>2</sub> and HEC. Another metallized gelled MMH fuel was NOTSGEL-A. NOTSGEL-A consisted of MHF-3, aluminum, and gelling agents. A series of stable suspensions called NOTSGELS have been prepared by suspending metal additives in hydrazine fuel blends, such as MHF-3, and preparation, rheological properties, density, mechanical stability, thermal stability, storage stabilities, and shipboard storage tests were discussed. Other metallized MHF-3 gels contained boron powder instead of aluminum and their expulsion properties were tested as well [893].

# Nitramines

## Nitramines

Nitramines are discussed here in the volume on liquid fuels because they are derived from amines that are also contained in this volume and because the addition of one or more nitramine groups to the hydrocarbon skeleton is not sufficient to bring the molecule to stoichiometric or positive oxygen balances. The oxygen balances of all nitramines in this chapter are negative.

This chapter starts with a description of the open-chain, acyclic, linear alkyl-nitramines. The solid cyclic nitramines of more practical importance, such as RDX, HMX, and higher molecular mass nitramines are discussed in Sections 13 and 15.1 and their applications will be discussed in a future volume on solid propellant energetic materials. The current section of this chapter in the initial sections deals only with aliphatic, linear, acyclic nitramines, and is only an incomplete overview over some of the properties of these compounds. Some of these compounds were only prepared for kinetic or molecular structural studies, not as rocket propellants. These nitramines are of less practical importance as rocket propellants than the RDX and HMX and HNIW-type heterocyclic nitramines. Although they have the word “amine” in them, they don’t behave like the amines that we have come to know as hypergolic fuels in other chapters of this volume. They are more acidic than alkaline (caustic).

## 1 Alkylnitramines (Alkylnitroamines)

Substitution of one or more hydrogens from the nitrogen in the amino group of primary amines by nitro groups converts alkyl amines from bases into acids due to the electron drain by the nitro group away from the amino nitrogen; thus, the remaining hydrogen is released more easily. If only one nitrogen-bound hydrogen atom is replaced in an alkylamine, one obtains alkylnitramines (alkylnitroamines), and the remaining nitrogen-bound hydrogen N—H is quite acidic and forms stable salts with alkali metals and alkaline earth metals and some organic bases. The simple ( $C_{\leq 3}$ ) nitramines are liquids and are not typically used as explosives or propellant ingredients. They are prepared mostly for kinetic studies of the nitramine decomposition mechanism or as building blocks for other energetic compounds. Higher molecular weight liquid nitramines with low vapor pressures are used as energetic plasticizers in solid propellants.

### 1.1 Nomenclature of Alkylnitramines

Both terms nitramine and nitroamine are in use in the propulsion community. Neither one is fully IUPAC nomenclature compliant. The shorter term nitramine is preferred here, but if one conducts a literature search, it helps to use both spellings, without and with the extra letter “o.”

The location of nitro groups on the nitrogens that are part of an aliphatic amine can be identified by numbers or by placing apostrophe signs on the nitrogens as in *N,N'*-dinitroalkylenediamines if the compound contains two C—N—C nitrogen atoms or *N,N',N''*-trinitroalkylenetriamines if the compound contains three C—N—C nitrogen atoms and each of them carries an —NO<sub>2</sub> group.

When numbers are used, which is the more systematic way of nomenclature, the numbers indicate the location of the nitrogen atoms in the hydrocarbon chain with the term “aza” such as in 2,4-diazapentane for methylene-di(aminomethyl)-amine and numbers indicate the location of the nitro groups as in 2,4-dinitro-2,4-diazapentane or 2,4-dinitro-2,4-diazaheptane.

If there are other substituents (azido, chloro, hydroxy, nitro, nitroxy) on the alkyl groups that are linked to the —N(NO<sub>2</sub>)— nitramine, they should be listed in accordance with IUPAC regulations in the sequence of priority or in alphabetical order.

The words nitro and aza are sometimes combined to form the term nitraza. To add to the confusion about proper nomenclature for nitramines, compounds like di-*n*-propylnitramine  $\text{H}_3\text{C}-\text{CH}_2-\text{CH}_2-\text{N}(\text{NO}_2)-\text{CH}_2-\text{CH}_2-\text{CH}_3$  were once supposed to be named di-*n*-propylnitramide for indexing purposes. This compound could also be called 4-nitrazaheptane. Nitramide (nitramine),  $\text{H}_2\text{NNO}_2$ , is the parent compound of all alkyl and aryl nitramines but it is unstable, as is its dinitro analog, dinitramide (dinitramine),  $\text{HN}(\text{NO}_2)_2$  [1].

### 1.2 Literature about Alkylnitramines

A historical summary on nitramines, a sometimes forgotten, but very useful resource collecting dust on some book shelves, included information on ethylenedinitramine, propylenedinitramine, pentaerythrityl tetranitramine, 1,2,3-trinitrazapropane, *N*-(β-nitroxyethyl)nitramine (NENA), *N*-(β-trinitroxyethyl)methylnitramine (MeNENA), *N*-(β-trinitroxyethyl)ethylnitramine (EtNENA), *N,N*-bis(β-nitroxyethyl)nitramine (DINA), and several similar compounds, including physical and sensitivity properties and methods of preparation [2]. Although very old, it still contains some useful information.

Aliphatic nitramino alcohols, 2-nitro-2-aza-alkan-1-ols,  $\text{RN}(\text{NO}_2)\text{CH}_2\text{OH}$ , as well as their ethers and esters, are useful intermediates in the synthesis of other nitramines. The general method for synthesis of nitramino alcohols is the reaction of primary nitramines with formaldehyde, with an *N*-alkyl-*N*-hydroxymethyl-nitramine as an intermediate [3].

Methods of making primary aliphatic nitramines were reviewed in a summary with 207 references covering literature up to the end of 1967 [4]. In that summary, in addition to the well-known traditional methods for the preparation of nitramines, little known methods for making them were examined and prospects for their further development were discussed.

Primary aliphatic nitramines can be prepared by a four-step procedure [5]: (1) acylation of the parent alkyl amine to form a urethane, (2) nitration of the urethane, (3) ammonolysis of the *N*-nitrourethane, and (4) acidification to release the free nitramine from its ammonium salt.

Synthetic routes to *N*-nitro compounds are summarized in an excellent book by Agrawal and Hodgson [6]. For instance, chapter 5, *Synthetic Routes to N-Nitro Functionality* (pp. 191–261, with 221 references) describes many synthetic routes to nitramines. Chapter 6 of the same book lists *Energetic Compounds 2: Nitramines and Their Derivatives* (pp. 263–291, with 92 references). It was found that only weakly basic amines can be nitrated under highly acidic conditions. Strong amine bases are largely protonated under such conditions with the positive charge on nitrogen repelling electrophilic nitrating species, whereas weaker bases have a higher proportion of free amine base present under the same conditions. Thus, very weakly basic amines or those with a poor affinity for protons are nitrated (“nitraminated”) more readily than stronger bases. See also [7].

### 1.3 Physical Properties of Alkylnitramines

As an introduction, here we summarize literature references that deal with physical properties of nitramines as a group instead of individual chemical compounds. This is an opportunity to study the effect of the location of the nitramine group in the molecule on the properties of the nitramine and compare the properties. Properties of some of the more important individual nitramine compounds will be summarized in subsequent sections.

#### 1.3.1 Melting Points of Alkylnitramines

It is important to know the exact melting points of nitramines because the melting points often coincide with incipient decomposition. Nitramines are used as explosives, energetic additives to propellants, and as energetic plasticizers. Most nitramines melt at very high temperatures that prevent their use as castable explosives. Most

nitramine explosive charges have to be pressed or plasticized to formulate a PBX which is easier to form to the desired shape of an explosive charge, such as in a shaped charge. Other nitramines are used as plasticizers and in this instance it would be desirable to have a low melting point to make the compounds processable at room temperature.

Melting points of nitramines can be predicted roughly by an empirical method based on molecular mass and molecular structure [8]. The average deviation of predicted temperature from measured temperatures was 5.4% (see also [9]). These methods are based on the elemental composition of energetic compounds and the contributions of some specific polar groups/structural moieties as additive and nonadditive functions, respectively.

### 1.3.2 Densities of AlkylNitramines

For some applications of alkylnitramines, such as in explosives, the density is an important performance parameter. Densities of alkylnitramines can be determined experimentally and several measured data for individual compounds are listed further down, or can be predicted theoretically. One of the first predictive methods was based on the group additivity method [10], comparing predictions for 173 energetic compounds with experimental results.

Correlations to predict density based on two different models were introduced for 82 different energetic compounds including 5 acyclic and cyclic nitramines, 9 nitrate esters, and 13 nitroaliphatic compounds whose molecules contained functional groups common to CHNO explosives [11–13]. Additional work expanded the list of energetic materials to 172 compounds [14]. Root mean square (rms) deviations for acyclic and cyclic nitramines were worse than for nitrate esters and nitroaliphatic explosives. This method is a simple procedure for calculating density of energetic compounds and gave good results as compared to group additivity methods for estimating the density of organic explosives.

Another efficient and convenient method for predicting the crystalline densities of energetic nitramines was established based on quantum chemical computations [15]. Density functional theory with four different basis sets and various semiempirical molecular orbital methods have been employed to predict the molecular volumes and densities of a series of energetic nitramines including acyclic, monocyclic, and polycyclic/cage molecules. The densities predicted by the semiempirical MO methods were all higher than the experimental data.

### 1.3.3 Thermodynamic Properties of Nitramines

#### 1.3.3.1 Enthalpies of Formation of AlkylNitramines

The enthalpies of formation of several acyclic alkylnitramines are listed in Table 1.

Enthalpies of formation of condensed phase nitramines, nitrate esters, nitroaliphatics, and related energetic compounds which contain at least one of the

**Table 1:** Enthalpy of formation of alkylnitramines.

| Compound name                                       | Gross formula                                                | Molecular mass |         | Enthalpy of formation |         |          |        |
|-----------------------------------------------------|--------------------------------------------------------------|----------------|---------|-----------------------|---------|----------|--------|
|                                                     |                                                              | g/mol          | mol/kg  | kcal/100 g            | kcal/kg | kcal/mol | kJ/mol |
| Ethyl nitramine                                     | C <sub>2</sub> H <sub>6</sub> N <sub>2</sub> O <sub>2</sub>  | 90.08          | 11.1012 | -22.85                | -228.5  | -20.58   | -86.1  |

Data sources: [16,17]

functional groups including N—NO<sub>2</sub>, C—ONO<sub>2</sub> or nonaromatic C—NO<sub>2</sub> can be interpolated from a collection of measured heats of combustion of different energetic materials based on elemental composition and various structural and functional group parameters of CHNO energetic compounds [18]. Enthalpies of formation for 78 energetic compounds including nitramines, nitrate esters, or nitroaliphatics were calculated by an empirical formula and compared with experimental data. The root mean square (rms) deviations for 19 well-known energetic compounds were also compared with results from complex quantum mechanical computations which showed very similar rms deviations of 23.8 and 21.3 kJ/mol for empirical and quantum mechanical calculation methods, respectively. Predicted condensed-phase heats of formation for other 59 energetic molecules with complex molecular structures had significantly more scatter with an rms deviation of 42.3 kJ/mol from experimentally measured heats of formation. This method can provide reliable predictions for energetic compounds compared to the calculated outputs of the best empirical and complex quantum mechanical methods [19].

The enthalpies of formation in the standard (liquid or solid) state and in the gas phase of a series of secondary nitramines, including dimethyl-EDNA, were calculated on the basis of the experimental energies (enthalpies) of combustion and vaporization measurements [20]. The enthalpies of combustion of nitramines were calculated from the energies of combustion measured with a calorimeter and the enthalpies of vaporization were experimentally measured for 13 substances with a microcalorimeter. An analysis of the main thermochemical values (the enthalpies of formation in the gas phase and the enthalpies of evaporation) showed that the energy properties of the nitramine group are independent of the structure of the molecules studied and of the number of functional groups in them. Table 2 presents data for the heat of combustion, enthalpies of formation in the solid and vapor state and the heat of evaporation (sublimation) of dialkylnitramines. The enthalpies of formation of the alkylnitramine radicals made it possible to calculate the bond dissociation energies in the nitramines and their radicals of different structures. It was shown that all alkyl dinitramines stud-

ied decomposed via the radical mechanism with the elimination of the  $\text{NO}_2$  group at the first stage (Section 17.3). Therefore, if data on the enthalpies of formation in the gas phase are available, the enthalpies of formation of radicals of the  $\text{RN}\bullet\text{NO}_2$  type and the bond dissociation energies of the nearest environment of the  $\text{N}-\text{NO}_2$  group can be calculated.

### 1.3.3.2 Heats of Combustion of Nitramines

A similar method was described for estimating the gross and net (upper and lower) heats of combustion of energetic compounds, including acyclic and cyclic nitramines [21]. Elemental compositions as well as the presence of some specific polar groups and molecular fragments are important parameters in that model. A comparison of the predicted results with measured data showed that this method gave reliable predictions of heats of combustion with respect to group additivity method and computed values based on atom-type electrotopological state indices for several energetic compounds where the model can be applied.

### 1.3.3.3 Heats of Fusion of Alkylnitramines

A similar interpolation method was used for the prediction of the heats of fusion of nitramines [22]. Heats of fusion of some nitramines, averages formed from measured values gathered from several different sources in the literature, are summarized in Table 3.

**Table 3:** Heat of fusion of nitramines.

| Compound name                                                     | Heat of fusion |          |
|-------------------------------------------------------------------|----------------|----------|
|                                                                   | kJ/mol         | kcal/mol |
| 1,3-Dinitro-1,3-diazacyclobutane (TETROGEN)                       | 26.32          | 6.29     |

Data source: [22] and from literature data

Similar methods for predicting the heat of sublimation of nitramines are based on empirical comparison and identification of the contributions by functional groups [23].

### 1.3.4 Molecular Structure of Nitramines

The high polarity of the nitro group in nitramines contributes to the relatively high melting points of nitramines and their tendency to form adducts among themselves

or with other compounds. Many studies have been conducted to better understand the relationship between molecular structure of nitramines and their melting points and thermal stability. Most nitramines start decomposing as soon as they melt.

The CNDO/2 electronic structure of nitramines was used to explain their tendency toward self-association and complexation with phenol via hydrogen bonding [24]. The charge distributions within 19 nitramines indicated that complexation involved the O atoms of the NO<sub>2</sub> group. The heat of self-association of secondary nitramines exceeded that of primary ones.

### 1.3.5 Bond Energies of N—N Bonds in Nitramines

An *ab initio* SCF computational study of six nitramines R<sub>1</sub>R<sub>2</sub>NNO<sub>2</sub> has been carried out with the objective of gaining a better understanding of how the properties (bond orders, dipole moment, and electrostatic potential) of the >N—NO<sub>2</sub> group are affected by the natures of R<sub>1</sub> and R<sub>2</sub> [25]. In most instances, the >N—NO<sub>2</sub> portions of the molecules are planar, due to the strong electron-withdrawing effect of the nitro group. One consequence is that the N—NO<sub>2</sub> bonds possess some degrees of double bond character. Their bond orders range from 1.36 to 1.63, with the weaker bonds corresponding to the more electron-withdrawing R<sub>1</sub> and R<sub>2</sub> group. The strong negative electrostatic potentials normally associated with the lone pairs of amino-type nitrogens are greatly weakened or eliminated in most of these molecules and several of them show evidence of significant hyperconjugation, resulting in enhanced acidity.

The structure, electron density distribution, energetic, and electrostatic properties of simple nitramine-based energetic molecules were determined using density functional theory [26]. In the NO<sub>2</sub> group substituted molecules, the N—N bond distance increased with the increase of NO<sub>2</sub> groups, whereas in C—N bonds, this effect is smaller, and the distances are almost equal. The topological analysis of electron density reveals that the electron density of C—N and N—N bonds are significantly decreasing with the increase of NO<sub>2</sub> groups in the nitramine molecules. The charge concentration decreases with the increase of NO<sub>2</sub> groups, which leads to weakening of the N—N bonds in the molecules. Computational chemistry may aid in the molecular design of more energetic and/or more stable nitramines [27].

### 1.3.6 Optical Properties of Nitramines

The UV absorption bands associated with nitramino groups have been investigated in a variety of compounds of known structure [28]. The groups may be characterized by the UV spectrum, and the number of each type of group present in a given compound may be estimated from an analysis of the shape and intensity of the absorption spectrum. These correlations have been applied to the elucidation of the structure of new compounds isolated in the course of an investigation of the chemistry of RDX.

A number of nitramines, including methylenedinitramine, ethylenedinitramine, nitrourea, nitrourethane, nitroguanidine, and RDX were prepared, purified and their UV and IR spectra examined for future analysis applications [29]

It was shown that the use of *ab initio* harmonic force fields, IR and Raman intensities, and depolarizations made possible a rigorous interpretation of the experimental spectra of the simplest aliphatic nitramines  $\text{H}_2\text{NNO}_2$ ,  $\text{CH}_3\text{NHNO}_2$ ,  $(\text{CH}_3)_2\text{NNO}_2$ , and their isotopomers [30, 31]. Some common patterns of the geometrical parameters, vibrational spectra and force fields of the simplest nitramines can be seen. The scale factors, which were introduced to correct for systematic errors by fitting the parameters to the observed frequencies, were mutually adjusted during the solution of the inverse vibrational problem and can be used to analyze spectra of larger molecules.

Vibrational spectra of several nitramines in the long-wave region ( $50\text{--}450\text{ cm}^{-1}$ ) show the self-association of nitramines [32]. The frequencies of intra- and intermolecular vibrations need to be separated to achieve a tentative assignment of the frequencies of self-associative complexes.

## 1.4 Chemical Properties of Nitramines

### 1.4.1 Reactions of Nitramines

The pre-eminent reaction of primary nitramines is that of salt formation with bases. There are hundreds of salts of nitramines described in the literature and many qualify as energetic materials. There are studies on the  $\text{pK}$  of nitramines as a functions of molecular structure, but those are mostly of academic interest and not reviewed here. Condensations of primary aliphatic nitramines with formaldehyde, aided by 90% sulfuric acid, lead to methylenebis(nitramines) [33]:

### 1.4.2 Decomposition of Nitramines

A review of the thermal decomposition of *N*-nitro-compounds based on a list of 108 literature references indicated that a nonchain radical mechanism with cleavage of the  $\text{N--NO}_2$  bond in the rate-determining step is the most probable mechanism [34]. A systematic summary of kinetic parameters of the thermal decomposition of *N*-nitro-compounds supported this conclusion.

A manometric method combined with GC and GC/MS was used for detailed analysis of kinetics and products of thermal decomposition for the homological series of primary nitramines in the melted state with general formula  $\text{R--NHNO}_2$ , where  $\text{R} = \text{Me}$ ,  $\text{Et}$ ,  $n\text{-Pr}$ ,  $n\text{-Bu}$ ,  $i\text{-Bu}$ ,  $\text{tert-Bu}$ ,  $\text{O}_2\text{NHN}(\text{CH}_2)_3$ ,  $\text{NC}(\text{CH}_2)_2$ ,  $\text{O}_2\text{NHNCH}_2$ ,  $\text{O}_2\text{NHNCH}_2\text{N}(\text{NO}_2)\text{CH}_2$ , with the objective to determine how the nitramine structure influences decomposition rate [35]. Arrhenius equation parameters of the decomposition reactions were in the range  $E_a = 106.3\text{--}129.9\text{ kJ/mol}$  and  $\log A = 9.55\text{--}12.72$ . A linear correlation was found between the decomposition rate constant logarithm and nitramines  $\text{pK}_a$  and indicated that the primary step in nitramine thermal decomposition is ionization. The proposed mechanism of thermal decomposition was based on ionization and the following decomposition of a nitramine molecule, protonated by amino nitrogen.

Kinetics and activation parameters of the solution thermolysis of the three nitramines: dimethylnitramine, diisopropylnitramine, and *N*-nitropiperidine were determined over the temperature range 473–573 K (200–300 °C) in different solvents and compared to some isotope-labeled nitramines [36]. Each formed the corresponding nitrosamine as the only, or major, condensed phase product. For dimethylnitramine the products were completely characterized. The rate-determining step was homolysis, the N–NO<sub>2</sub> bond being the most obvious point for first attack.

The thermal decomposition of various types of nitramines (acyclic, cyclic, and multifunctional) was examined experimentally by analyzing 13 different nitramines in solution and in the melt [37, 38]. The nitramines included acyclic mononitramines [dimethylnitramine (DMN), diethylnitramine (DEN), dipropylnitramine (DPN), and diisopropylnitramine (DIPN)], cyclic mononitramines [*N*-nitro-piperidine (NPIP) and *N*-nitropyrrolidine (NPyr)], cyclic dinitramines [*N*-dinitropiperazine (pDNP), 1,3-dinitro-1,3-diazacyclopentane (DNI), and 1,3-dinitro-1,3-diazacyclohexane (mDNP)], and 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX), octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine (HMX), hexanitro-hexaazaisowurtzitane (HNIW), and 1,3,3-trinitroazetidine (TNAZ). For the acyclic and cyclic mono- and di-nitramines, the corresponding nitrosamines were the only or major condensed-phase product. By comparing the results and the molecular structures of the nitramines, certain trends which increased the rate of decomposition were observed, such as (1) increasing carbon chain length, (2) increasing the number of nitramine functionalities, (3) situating the dinitramine groups in meta position to each other, and (4) decreasing the ring size (increasing the ring tension). Since all the nitramines exhibited first-order decomposition and activation energies in the range 188–230 kJ/mol (45–55 kcal/mol), it was postulated that the triggering mechanism remains N–NO<sub>2</sub> homolysis even in complex nitramines. The internal hydrogen transfer mechanism postulated for dimethylnitramine also appears to be operative in the more complex species.

The decomposition of most nitramines is dependent on pressure. The decrease of reaction rate with increasing pressure was presumed to indicate that homolysis of the N–NO<sub>2</sub> bond is the rate-determining step of the process [39].

DSC thermograms of eight linear and seven cyclic nitramines predominantly with methylenenitramine groupings were measured, and a linear relationship was found between the onset of endotherm or peak temperatures of melting of these compounds and the melting points of their aliphatic structural analogues (i.e., hydrocarbon homomorphs with no heteroatoms) [40]. A similar relationship between the corresponding heats of fusion was discovered. On the basis of these facts, the melting points and heat of fusion were predicted for a series of cyclic nitramines.

The mechanism of decomposition of nitramines has been studied theoretically using quantum chemical methods to calculate the heats of formation and free energies of the nitramines H<sub>2</sub>NNO<sub>2</sub> and CH<sub>3</sub>NHNO<sub>2</sub> as well as of some molecular radical species which might arise from the decomposition process [41]. The thermochemical properties of transition state activated complexes, the bond energies, and dissociation en-

ergies obtained from these calculations were used to determine decomposition pathways of more important propellant nitramines such as HMX and RDX. The results indicated that at high temperatures, bond fission of the nitro group (with a bond energy of  $\sim 200$  kJ/mol) should play an important role as the initial decomposition step. At lower temperatures, the five-centered HONO elimination with a dissociation energy of  $\sim 170$  kJ/mol is possible but has a small pre-exponential factor compared to experimental decomposition rates. Another decomposition mechanism, involving attack by autocatalytic generated H atoms, which provides a lower energy pathway ( $\sim 128$  kJ/mol) with nitrosamines as intermediates can lead to  $N_2O$  formation. The H atom attack can also lead to HCN and  $NO_2$  formation through pathways analogous to the initial N— $NO_2$  bond breaking process.

The thermal decomposition of 1,4-dinitropiperazine and 1,4,4-trinitropiperidine was compared to that of other nitro compounds and difluoroamino compounds [42]. Geminal bis(difluoroamino) compounds appeared to be somewhat more stable than the corresponding *gem*-dinitro compounds, although they released more heat during decomposition. The decomposition of *gem*-bis(difluoroamino) and *gem*-dinitro compounds exhibited similarities. Both experienced loss of one geminal  $NX_2$  group followed by the rearrangement of the remaining  $-NX_2$ . Where a nitramine functionality was present, the nitroso analogue was observed as a major decomposition product.

A critical review of the published data on the mechanism of decomposition of secondary nitramines concluded that the first step of decomposition always includes cleavage of the N— $NO_2$  bond, which is followed by various secondary reactions and sometimes by chain reaction processes [43].

A method to predict activation energies of thermal decomposition of nitramines by interpolation showed that the activation energies of acyclic nitramines can be expressed as a function of optimized elemental CHNO composition [44]. The method was applied to cyclic nitramines that contain more than five members. The root mean square (rms) and the average deviations were 5.67 and 3.98 kJ/mol, respectively, for 14 known nitramines with different molecular structures. The method was also tested with moderate success for 2,4,6,8,10,12-hexanitro-2,4,6,8,10,12-hexaazaisowurtzitane (HNIW) and 4,10-dinitro-2,4,6-tetroxa-4,10-diaazaisowurtzitane (TEX).

### 1.4.3 Analysis of Nitramines

Analytical methods for nitramines are important for quality control of nitramine energetic materials and for the detection of traces of nitramines in places where they do not belong, e.g., the baggage of airline travelers. Nitramines can be analyzed by thin layer chromatography and the separated spot can be made visible by spraying with diphenylamine and illuminating with UV for 30 min. [45].

A review paper summarized the available analytical methods in the open literature for the determination of some aliphatic and cyclic nitramines [46]. Since the nitramines are found in complex matrices and/or in very low concentrations, an ex-

traction step is often necessary before their determination. Liquid–liquid extraction using dichloromethane and solid phase extraction with an activated carbon-based adsorbent have been the two most common extraction/trapping methods.

### 1.5 Explosive Sensitivity of Nitramines

A relationship was found between the 50% initiation probability drop weight impact sensitivity of 16 nitramines, on the one hand, and heats of fusion,  $^{15}\text{N}$  NMR chemical shifts of aza atoms in reaction centers, parameters of low-temperature thermolysis, and oxygen balances of nitramines studied, on the other hand [47]. Several drop weight impact sensitivity values were predicted for other nitramines. The impact sensitivity of nitramine molecules depends on the electronic configuration within their reaction centers and on their conformational stability and intensity of their intermolecular interactions. The reaction centers are the same as in the case of initiation of the nitramines by explosive shock.

For groups of nitramines and nitroaliphatics, taken separately, it was shown that shock sensitivity is related to the strengths of all  $\text{N}-\text{NO}_2$  and/or  $\text{C}-\text{NO}_2$  bonds in the molecules, taken in conjunction with their overall sizes [48]. The reciprocals of the bond lengths were used as measures of bond strengths, while molecular mass was taken as the indicator of molecular size. Linear correlation coefficients of 0.94 and 0.98 were obtained, respectively, for nitramines and nitroaliphatics of a variety of structural types. These results are indicative of the importance of the  $\text{N}-\text{NO}_2$  and  $\text{C}-\text{NO}_2$  bonds in the shock-induced decomposition of nitramines and nitroaliphatics.

The electrostatic discharge sensitivity of nitramines may be related to their detonation pressure [49] or their molecular structure [50]. Spark sensitivity of explosives is an important area of investigation. Numerous accidental explosions have been triggered by an electrostatic discharge. Therefore, correlations were sought between the spark sensitivity and certain molecular orbital characteristics of some nitramine type explosives, such that the spark sensitivity of yet untested energetic materials could be predicted from the known properties or similar, related chemical compounds [51]. As a start of that project, semi-empirical and DFT calculations were carried out and investigations revealed that the nitramines undergo decomposition in the electric field mainly via their anionic states.

A simple model for prediction of the relationship between friction sensitivity and activation energy of thermolysis of cyclic and acyclic nitramines on the basis of their molecular structures assumed that friction sensitivity of an energetic  $\text{CHNO}$  compound can be expressed as a function of activation energy of thermolysis and the contribution of specific molecular structural parameters [52]. For a group of 21 nitramines with different molecular structures, the root mean square and the average standard deviations were 14.2 and 17.8 N, respectively, as compared to experimental values.

## 2 Mononitramines

This section deals mostly with specific aliphatic nitramines that contain only one nitro group on the amino group. The name dinitramine can be ambiguous, as the two nitro groups can be either attached both to the same nitrogen that was once an amine, or they can be attached to two separate nitrogen atoms, usually at the end of an alkane chain. There are only few aromatic nitramines of significance. Tetryl is one of them. Isocyclic, alicyclic, and heterocyclic nitramines are discussed in Sections 11 through 16.

This first section is on open-chain (acyclic, linear) alkylnitramines (also called alkylnitroamines), such as diethylnitramine  $\text{C}_2\text{H}_5\text{N}(\text{NO}_2)\text{C}_2\text{H}_5$ . These nitramines can be used as model substances for the study of decomposition of other, more complex nitramines. The higher molecular mass open-chain alkylnitramines can be used as plasticizers for double-base solid propellants.

### 2.1 Methylnitramine and Dimethylnitramine

#### 2.1.1 Methylnitramine

Methylnitramine, also known as  $\text{H}_3\text{CNHNO}_2$ ,  $\text{C}_1\text{H}_4\text{N}_2\text{O}_2$ , *N*-methylnitramine, methyl-nitroamine, monomethylnitramine; methanamine, *N*-nitro-; CAS RN [598-57-2], is unstable and shock sensitive. Methylnitramine forms clear, needle-shaped crystals, melting at 311 K (38 °C), which start to decompose about 433 K (160 °C). Other sources give the melting point as 308 K (35 °C) and the decomposition temperature as 359 K (86 °C). It is an especially effective sensitizer for explosives because it has an explosive group ( $-\text{NHNO}_2$ ) which is resistant to hydrolysis in solution. It is very soluble in water and it is underoxidized with an oxygen balance of  $-42\%$ .

Methylnitramine can be prepared by nitrating dimethylurea with a mixture of sulfuric acid and nitric acid with subsequent separation of 1,3-dimethyl-1,3-dinitrourea by the use of a solvent with recovery of a dimethyldinitrourea in organic solvent, with hydrolysis of the dimethyldinitrourea with hot water to yield methylnitramine [53]. Methylnitramine decomposes explosively when in contact with concentrated sulfuric acid. Another method for preparation of alkylnitramines starts with nitration of alkyl amides like *N*-monosubstituted formamide [54]. This method is also suitable for synthesis of methylenedinitramine from a bis-amide. Another method for the preparation of methylnitramine is the addition of *N,N*-dimethyl-*N,N*-dinitrooxamide to a solution of ammonia at 273 K (0 °C).

Methylnitramine,  $\text{CH}_3\text{NHNO}_2$ , or *aci*-methylnitramide has been suspected to be an intermediate in the thermal decomposition of methylammonium nitrate [55]. If methylnitramine is an intermediate, the weakest bond ( $\text{N}-\text{NO}_2$ ) should break first.

Methylnitramine has been investigated mostly as a model substance for other (more stable) nitramines and as an intermediate in the decomposition of RDX or HMX.

It was studied mostly in the vapor phase and due to its hazardous nature it is rarely prepared in the liquid state. Some of the studies were strictly theoretical in nature and avoided handling the material. The principal reactions of the primary event of *N*-methylnitramine unimolecular decomposition have been investigated, and the results indicated various reaction mechanisms [56].

Calculations of the complex potential energy surface and reaction mechanisms for the unimolecular isomerization and decomposition of methylnitramine indicated that there are four low-lying energy routes: (1) the N–N bond fission pathway; (2) a sequence of isomerization reactions via  $\text{CH}_3\text{NN}(\text{OH})\text{O}$ ; (3) the HONO elimination pathway; (4) the isomerization and the dissociation reactions via  $\text{CH}_3\text{NHONO}$  [57]. The rate constants of each initial step (rate-determining step) for these channels and the Arrhenius expressions of the channels over the temperature range 298–2000 K were calculated. The calculated overall rate constants was  $6.9 \times 10^4$  at 543 K, which was in good agreement with experimental data. Based on the analysis of the rate constants, the dominant pathway should be the isomerization reaction to form  $\text{CH}_3\text{NN}(\text{OH})\text{O}$  at low temperatures, while the N–N bond fission and the isomerization reaction to produce  $\text{CH}_3\text{NHONO}$  are expected to be competitive with the isomerization reaction to form  $\text{CH}_3\text{NN}(\text{OH})\text{O}$  at high temperatures.

The dissociation energies of N–NO<sub>2</sub> bonds of primary and secondary *N*-nitramines have been investigated using nonempirical methods and DFT methods [58]. The basic tendencies in the changes of the geometrical and electronic structures, formation enthalpies, and dissociation energies were then analyzed in a homologous series of nitramines differing only by  $-\text{CH}_2-$ . Various alternative mechanisms of the gas-phase monomolecular thermal decomposition have been studied based on the example of *N*-methylnitramine decomposition. Decomposition by way of the aci-form formation and its further multistage destruction is the most probable way of decomposition of the primary *N*-nitramines.

Stable salts are formed between monomethylnitramine (methylnitroamine) and alkali or alkaline earth metals. The IR and Raman frequencies of the  $\text{K}^+$ ,  $\text{Rb}^+$ ,  $\text{Cs}^+$ ,  $\text{Me}_4\text{N}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Ba}^{2+}$ , and  $\text{Mg}^{2+}$  salts of  $\text{MeNHNO}_2$  were not appreciably affected by the cation or by transition from the crystalline state to solution [59].

*N*-methylnitramine forms needle-shaped orthorhombic crystals. The crystal structure of methylnitramine is space group *Pbca* with the cell parameters of  $a = 8.865(4) \text{ \AA}$ ,  $b = 6.673(3) \text{ \AA}$ ,  $c = 11.324(6) \text{ \AA}$ ,  $\alpha = 90^\circ$ ,  $\beta = 90^\circ$ ,  $\gamma = 90^\circ$ ,  $V = 669.9(6) \text{ \AA}^3$ ,  $Z = 8$ , and  $\rho_{\text{calcd.}} = 1.508 \text{ g/cm}^3$ . *N*-Methylnitramine is a weak acid with  $\text{p}K_{\text{a}} = 6.0$ . Three tautomeric forms are responsible for the acidity of *N*-methylnitramine.

*N*-methylnitramine forms alkali metal, earth-alkaline metal, and transition-metal salts, and also forms stable salts with ammonia, hydrazine, hydroxylamine, guanidine, and aminoguanidine [60, 61]. The Mannich reaction of *N*-methylnitramine with formaldehyde yields 2-nitro-2-azapropanol, which can be used for the synthesis of other energetic compounds.

### 2.1.2 Dimethylnitramine

Dimethylnitramine, also known as *N*-nitrodimethylamine, 2-nitro-2-azapropane, *N,N*-dimethylnitramine,  $\text{H}_3\text{C-N}(\text{NO}_2)\text{-CH}_3$ , DMN, DMNA, CAS RN [4164-28-7] is one of the simplest alkylnitramines with a melting point of 322–326 K (49–53 °C) and a density of 1.109 g/cm<sup>3</sup>.

Dimethylnitramine can be prepared by adding a highly concentrated (90%) dimethylammonium nitrate/water solution to acetic anhydride containing 1% hydrochloric acid as a catalyst at a temperature of 313 K (40 °C). Excess acetic anhydride must be converted to acetic acid and removed by distillation. The yield of DMN is 70% as based on dimethylammonium nitrate. Dimethylnitramine can also be prepared by reaction of nitryl chloride with lithium dimethylamide.

Dimethylnitramine is closely related to dimethylnitrosamine, a potent carcinogen that can form during pyrolytic decomposition of cured meat and some vegetables. Both are the most troublesome products of partial combustion and environmental deterioration of unsymmetrical dimethylhydrazine (UDMH). UDMH was once made by reduction of dimethylnitrosamine and could also be made by reduction of dimethylnitramine. It was stated that dimethylnitramine as the intermediate for UDMH production is less toxic than dimethylnitrosamine.

The heat of combustion of DMN is  $376.1 \pm 1.0$  kcal/mol determined calorimetrically, which corresponds to a standard enthalpy of formation of  $-71.1 \pm 4.2$  kJ/mol ( $-17.0 \pm 1.0$  kcal/mol) [62]. From the same source, the heat of combustion of diethylnitramine is  $-692.4 \pm 2.0$  kcal/mol determined calorimetrically, which corresponds to a standard enthalpy of formation of  $-105.8 \pm 8.4$  kJ/mol ( $-25.3 \pm 2.0$  kcal/mol).

Dimethylnitramine melts at 329–330 K (56–57 °C). In the DSC, DMN begins to melt at 328.3 K with a peak at 330.9 K and the heat of fusion is 17.24 kJ/mol [40]. The density of DMN is 1.090 g/cm<sup>3</sup> and its enthalpy of formation is  $-72.4$  kJ/mol ( $-17.3$  kcal/mol =  $-192$  cal/g).

Because DMN is one of the simplest nitramines, it often has been studied as a model compound to elucidate the decomposition mechanisms of other more complex and economically more important nitramines. The kinetics and mechanism of the thermal decomposition of DMN and dimethylnitrosamine have been studied at high temperatures in a shock tube with IR, laser, and UV diagnostics and at lower temperatures in a static system [63]. The understanding of the chemistry of these model compounds is an important step toward a better understanding of the complex

mechanism of decomposition and burning characteristics of larger nitramines such as RDX and HMX.

The kinetics and mechanism of the thermal decomposition of DMN have been investigated at low temperatures (466–524 K) in a static system and at high temperatures (800–1200 K) in a shock tube with IR laser and UV diagnostics [64]. Detailed kinetic modeling has shown that the key initiation step is the dissociation of DMN into  $\text{NO}_2$  and the dimethylamino radical. The more energetic steps leading to CO were found to be a series of chain reactions starting from methyl radicals. One can extrapolate from this to a reaction scheme for the vapor phase thermal decomposition of RDX.

Dimethylnitramine has been extensively studied as a simple analog expected to exhibit some of the reactions important in cyclic nitramine decomposition. Much of the work on decomposition of nitramines centered around the scission of the N– $\text{NO}_2$  bond. The initial breakage of the N– $\text{NO}_2$  bond can be initiated thermally or, more selectively, by UV photolysis using monochromatic radiation. As a prototype for more complex nitramines, the gas-phase decomposition of DMN was studied in three laser-pyrolysis systems [65]. Results in two of these systems, unlike those reported in the literature, indicated that a nitro–nitrite rearrangement pathway is competitive with the expected (and previously invoked) N– $\text{NO}_2$  bond scission. This rearrangement pathway has been obscure because it can lead to some of the same products that are yielded by the bond scission route. The principal evidence for nitro–nitrite rearrangement includes the following: Arrhenius parameters for decomposition that are two orders of magnitude too low; molecular-beam, mass-spectrometrically sampled laser pyrolysis studies; and *ab initio* calculations that found a rearrangement pathway at slightly lower energy than that of simple bond scission. These results suggested that such rearrangement pathways may be a common feature of nitramine decomposition.

Tunable laser-induced fluorescence was used to probe the formation of ground state  $\cdot\text{OH}$ , NO and  $\text{NO}_2$  photoproducts [66]. These results provided new insight into the physical and chemical processes that occur in the decomposition of DMN.

For a comparison of thermally and photolytically initiated decomposition of DMN, the UV absorption of gas phase, room temperature dimethylnitramine was measured from 185 to 325 nm [67]. The spectrum had two distinct features whose maxima occurred at 193 nm (6.4 eV) and 230 nm (5.4 eV). Absorption cross-section at selected wavelengths between 185 and 325 nm were derived in accordance with Lambert–Beer law.

The photolysis of DMN was studied as a simple analog expected to exhibit some of the same processes important in cyclic nitramine decomposition [68]. The source of UV monochromatic radiation at 248 nm was an excimer laser.

A comprehensive scheme of the thermolysis mechanisms of methylnitramine and dimethylnitramine was derived using *ab initio* calculations, and the thermochemical preference of these or other possible decomposition reaction pathways were predicted and most energy-favored routes have been proposed [69, 70].

## 2.2 Ethylnitramine and Diethylnitramine

Dialkylnitramines can be prepared by reaction of a dialkylcarbonyl halides  $R_2NC(O)X$  with nitric acid in trifluoroacetic acid anhydride [71] or by reaction of dialkylcarbonyl halides with silver nitrate (only 28% yield). Diethylnitramine,  $(CH_3CH_2)_2NNO_2$ , crystals melt at 376–378 K (103–105 °C), have a refractive index of  $n_D^{25} = 1.4528$ , a density of 1.057 g/cm<sup>3</sup>, and can be purified by sublimation at 318 K at 80 Pa (45 °C at 0.6 mm Hg) or 388–391 K at 6.6 kPa (115–118 °C at 50 mm Hg). The heat of combustion of ethylnitramine, *N*-nitroethylamine,  $C_2H_5NHNO_2$ , is 1559 kJ/mol (372.5 kcal/mol) [72].

Diethylnitramine is the parent compound of a more energetic nitramine, diethylnitramine dinitrate (dinitroxyethyl nitramine, DINa) which is described in Section 4.8. Diethylnitramine  $(CH_3CH_2)_2NNO_2$  was chosen as a reference compound for density functional theory calculations to predict the heats of formation (HOFs) for various heterocyclic nitramine and  $R-NF_2$  compounds via designed isodesmic reactions [73].

## 3 Dinitramines

The name dinitramine is ambiguous because it does not identify whether the two nitro groups are attached to the same nitrogen (as in dinitramidic acid) or separate nitrogen atoms as discussed here. We should change the heading of this section to read “*N,N'*-Dinitramines” to make it clear that the compounds described in this category contain two nitrogens and each of those carries only one nitro group with an  $N-NO_2$  linkage.

For some applications of nitramines, such as plasticizers in double-base propellants, a lower melting point would be desirable. Lower melting points can be achieved by mixing several nitramines. Binary phase diagrams were measured by DSC for mixtures of methylnitramine with 2,4-dinitro-2,4-diazapentane and showed a eutectic temperature of 285.1 K at a eutectic composition with a methylnitramine mol fraction of 0.565, and a eutectic temperature of 280.3 K for a mixture of methylnitramine with 2,4-dinitro-2,4-diazahexane and a methylnitramine mol fraction of 0.653 [74]. For both systems simple eutectic behavior was observed.

### 3.1 Methylenedinitramine

Methylenedinitramine; also known as methanediamine, *N,N'*-dinitro-; *N,N'*-dinitromethylenediamine, 1,3-dinitro-1,3-diazapropane, *N*-(nitramidomethyl)nitramide, MEDINA,  $(NO_2)NHCH_2NH(NO_2)$ ,  $CH_2N_6O_4$ , CAS RN [14168-44-6],  $M = 136.067$  g/mol, is not thermally stable enough to be used as propellant or explosive ingredient [75]. It melts at 375 K (102 °C) with considerable decomposition [76]. The structure is similar to that of dinitrourea, CAS RN [176501-96-5], except the center of the molecule is formed by a methylene  $>CH_2$  group instead of a carbonyl  $>C=O$  group.

Methylenedinitramine

*N,N'*-Dinitrourea

Methylenedinitramine forms orthorhombic crystals with the unit cell parameters  $a = 9.06 \text{ \AA}$ ,  $b = 11.33 \text{ \AA}$ ,  $c = 5.09 \text{ \AA}$ ,  $Z = 4$ , and a measured density of  $1.735 \text{ g/cm}^3$ , compared to the calculated XRD density of  $1.72 \text{ g/cm}^3$  [77]. Nitration of a suspension of methylenediformamide in acetic anhydride with WFNA produced methylenedinitroformamide which on hydrolysis gave methylenedinitramine [78]. Methylenedinitramine can be stabilized by addition of picric acid or styphnic acid [79]. Methylenedinitramine is a useful intermediate in the synthesis of other nitramines, including cyclic nitramines [80].

Methylenedinitramine is an intermediate product of biodegradation of RDX. It forms stab-sensitive salts with heavy metal cations. The related compound *N*-methyldinitramine  $\text{H}_3\text{CN}(\text{NO}_2)_2$ , is discussed in Section 17. An IR spectrum of methylenedinitramine is shown in Figure 1

**Figure 1:** Infrared spectrum of methylenedinitramine. (Reproduced and modified from [81].)

### 3.2 Ethylenedinitramine

Ethylenedinitramine, also known as ethylenedinitroamine, *N,N'*-dinitroethylene diamine, tetranitroethylenediamine, *N*-(2-nitramidoethyl)nitramide, dinitroethylenediamine, EDNA, Halite, Haleite, 1,4-dinitro-1,4-diazabutane,  $(\text{CH}_2-\text{NH}-\text{NO}_2)_2$ ,

$\text{C}_2\text{H}_6\text{N}_4\text{O}_4$ , CAS RN [505-71-5],  $M = 150.0934 \text{ g/mol}$ , is a dibasic acid and forms salts with alkali metals and many organic nitrogen bases.

Ethylenedinitramine

Its applications as an energetic and nitrogen-rich additive in rocket propellant formulations will be summarized in a future set on solid propellants. As a military explosive, it possesses an advantage of combining high brisance with a comparatively low sensitivity. It was used together with TNT during World War II but is no longer used today. Another characteristic of EDNA is its relatively low explosion temperature.

Ethylenedinitramine is a relatively economic explosive. With an oxygen balance of  $-32\%$  for complete combustion to  $\text{CO}_2$ , it would require additional oxidizer to make full use of its fuel value in a rocket propellant.

### 3.2.1 Preparation of Ethylenedinitramine

Ethylenedinitramine can be prepared by nitration of ethyleneurea with mixed acid, to yield dinitroethyleneurea which then liberates carbon dioxide and forms ethylenedinitramine. The starting reactant ethyleneurea is prepared by reacting ethylene diamine with ethyl carbonate under elevated pressure.

Various methods were investigated for preparation of EDNA from ethylenediamine. EDNA has been prepared previously by hydrolysis of 1,3-dinitro-2-imidazolidone, which can be made by nitration of 2-imidazolidone. 2-Imidazolidone can be prepared by heating a mixture of anhydrous ethylenediamine and diethyl carbonate in a sealed tube, but the yield may be low and the product may be difficult to purify. Moreover, the preparation of anhydrous ethylenediamine is a tedious process. Instead, 2-imidazolidone can be obtained in 63% yield (based on the diethyl carbonate) from commercial aqueous 60–65% ethylenediamine without the use of a sealed-tube reaction [82]. A mixture of excess aqueous ethylenediamine and diethyl carbonate was heated, the excess reagents and water were removed by distillation, and the residue, presumably the ethylenemmonourethane  $\text{H}_2\text{NCH}_2\text{CH}_2\text{NHCOOC}_2\text{H}_5$ , was cyclized by the action of heat. In another method ethylenebisurethane, prepared from aqueous ethylenediamine and ethyl chlorocarbonate, was nitrated with 98% nitric acid, and the dinitroethylenebisurethane  $[\text{CH}_2\text{N}(\text{NO}_2)\text{COOC}_2\text{H}_5]_2$  was converted into EDNA in an overall yield of 87% by alkaline hydrolysis or by ammonolysis. The rapid rate of the reaction with aqueous ammonia at room temperature is noteworthy: in a few minutes the carbethoxy groups were removed and the water-soluble ammonium salt of EDNA was formed. The nitration of cyclic ethyleneoxamide with 98%  $\text{HNO}_3$  in acetic anhydride at 273–278 K ( $0\text{--}5^\circ\text{C}$ ) gave the cyclic dinitro

derivative *N,N'*-dinitropiperazine-2,3-dione, 1,4-dinitro-2,3-piperazinedione, CAS RN [165896-98-0], in good yield in the form of glistening prisms with m.p. 470–471 K (197–198 °C).

*N,N*-Dinitropiperazinedione

### 3.2.2 Physical Properties of Ethylenedinitramine

The physical properties of ethylenedinitramine are summarized in Table 4. An exhaustively detailed summary of properties of EDNA is provided in *Fedoroff Encyclopedia of Explosives*, volume 6 [83]. It also has information regarding properties of EDNA salts on page E243–E244. These salts can also be used as explosives or propellant ingredients. The US Army Material Command's *Engineering Design Handbook* contains a complete set of data on EDNA performance as an explosive [84].

**Table 4:** Physical properties of ethylenedinitramine.

| Property                     | SI units                | Other units                |                     | References |

**Figure 2:** Infrared spectrum of ethylenedinitramine. (Reproduced and modified from [81].)

**Figure 3:** Infrared spectrum of ethylenedinitramine. (Reproduced and modified from [29].)

Two very similar IR spectra for EDNA from two different sources are shown in Figures 2 and 3.

Ethylenedinitramine and tetramethylenedinitramine are homologues and their IR spectra are very similar. The IR spectra of crystalline ethylenedinitramine, tetramethylenedinitramine, and their perdeuterated derivatives were measured and assignments of the frequencies for the NH valence and deformation vibrations were made based on the isotope effect [89]. The bands in the IR spectra of these two compounds that experience the maximum shift as a result of deuteration must belong to the N—H bond. The bands at 1600 cm<sup>-1</sup> were once assigned to asymmetric valence vibrations of the nitro group which is incorrect.

Vibrational spectra of *N,N'*-dinitroalkylenediamines of the O<sub>2</sub>NNH(CH<sub>2</sub>)<sub>n</sub>NHNO<sub>2</sub> type for *n* = 1, 2, and 3 were measured for the natural nitrogen distribution and <sup>15</sup>N isotope-labeled compounds in the nitro group and deuterium-substituted amino

groups [90]. The isotope shifts in the absorption vibrational spectra allowed a more reliable assignment of most of the absorption bands.

The vibrational spectra of EDNA salts of the  $M^+ [^-N(NO_2)CH_2CH_2N(NO_2)^-]M^+$  ( $M = Li, Na, K, NH_4$ ) and  $[^-N(NO_2)CH_2CH_2N(NO_2)^-]M^{++}$  ( $M = Mg, Ni$ ) type were examined in aqueous solutions and in the solid state [91]. The frequencies of the nitramine moiety did not depend on the cation it was paired with, except for the  $Ni^{2+}$  salt, which may be coordinated differently. The differences in the IR spectra of the solid samples and the Raman spectra of solutions of the nickel salt and other salts of *N,N'*-dinitroethylene-diamine can be explained by the difference in the coordination of the cations.

The molar heat capacity of EDNA in the range from 200–448 K (–73 to +175 °C) can be described by the following linear equation

$$C_p = (3 \pm 0.8) + (0.13 \pm 0.003) \times T$$

where  $C_p$  is the molar heat capacity in  $\text{cal mol}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin [87]. The molar heat capacity of EDNA at 298 K is  $175.3 \text{ J mol}^{-1} \text{K}^{-1}$  ( $41.9 \text{ cal mol}^{-1} \text{°C}^{-1}$ ).

### 3.2.3 Chemical Properties of Ethylenedinitramine

EDNA is a dibasic acid and forms salts with alkali metals and many organic nitrogen bases. It is insoluble in ether, sparingly soluble in water and alcohol, and soluble in dioxane and nitrobenzene. EDNA is not hygroscopic. EDNA melts at 448 K (175–176 °C) and in the DTA thermogram, the maximum of the exotherm peak is at 475 K (202 °C) [92].

Methylene dinitramine,  $CH_2(NHNO_2)_2$ , MEDINA, and its homologue ethylene dinitramine,  $O_2NNHCH_2CH_2NHNO_2$ , EDNA are weak acids. The  $pK_a$  of MEDINA and EDNA in water are –4.8 and –5.9, respectively. They form salts with sodium hydroxide, potassium hydroxide, or hydrazine hydrate.

#### 3.2.3.1 Properties of Nitramine Salts

The enthalpies of combustion of the nitramines and their salts were measured in a bomb calorimeter and the enthalpies of formation calculated therefrom [93]. The results are summarized in Table 5. This table also contains the heats of solution of the compounds in water and the heats of dilution.

The diammonium salt of *N,N'*-dinitro-1,2-ethanediamine,  $[CH_2NNO_2(NH_4)]_2$ ,  $C_2H_{12}N_6O_4$ ,  $M = 184.15 \text{ g/mol}$ , melted at 452–453 K (179–180 °C), and in the DTA thermogram the maximum of the exotherm peak was at 464 K (191 °C) accompanied by a violent decomposition [94]. The enthalpy of formation of the diammonium salt of *N,N'*-dinitro-1,2-ethanediamine is  $-335 \text{ kJ/mol}$  ( $-80.10 \text{ kcal/mol} = -435 \text{ cal/g}$ ) [95].

The enthalpy of formation of the dihydrazinium salt of *N,N'*-dinitro-1,2-ethanediamine  $[CH_2NNO_2(N_2H_5)]_2$ ,  $C_2H_{14}N_8O_4$ ,  $M = 214.184 \text{ g/mol}$ ,  $\Delta H_f^{298} = -180.2 \text{ kJ/mol}$  ( $-43.07 \text{ kcal/mol} = -201 \text{ cal/g}$ ) [96].

**Table 5:** Enthalpies of formation, dissolution, and dilution of primary nitramines and their salts at 298 K.

| Compound formula                                                          | $\Delta H_f$       | $\Delta H_{sol}$ | $\Phi_L$ | $\Delta H_f$ (recommended) |
|---------------------------------------------------------------------------|--------------------|------------------|----------|----------------------------|
|                                                                           | kJ/mol             | kJ/mol           |          | kJ/mol                     |

Data Source: [93]

### 3.2.4 Safety Properties of Ethylenedinitramine

On the hot plate, EDNA explodes above the deflagration point temperature of 453 K = 180 °C = 356 °F. The impact sensitivity of EDNA in the Bundesanstalt für Materialforschung und -prüfung (BAM) impact sensitivity tester is 8 N m.

### 3.2.5 Toxicity of Ethylenedinitramine

The LD50 of EDNA in mice by oral administration was 540 mg/kg.

### 3.2.6 Explosive Performance of Ethylenedinitramine

In the lead block test a 10-g sample of EDNA exploding will create a cavity volume of 410 cm<sup>3</sup>. The detonation velocity of EDNA confined in a steel tube and compressed to a density of 1.65 g/cm<sup>3</sup> is 7570 m/s.

## 3.3 Alkyl-substituted Ethylenedinitramine Derivatives

Ethylenedinitramine is already a relatively stable nitramine, yet its stability can be improved by substituting one or two of the reactive hydrogens on the NH groups with methyl groups. The two methylEDNA compounds have been thoroughly characterized, but have not found practical applications.

Alkylation of EDNA with methyl iodide leads to *N*-methyl-ethylene-dinitramine (m.p. 394–395 K = 121–122 °C) and *N,N'*-dimethyl-ethylenedinitramine (m.p. 410 K = 137 °C). The drop weight sensitivity (50% point) of *N,N'*-dimethyl-ethylenedinitramine was 51 cm, less sensitive in comparison to that of RDX (50% = 35 cm). *N,N'*-Dinitro-*N*-methyl-1,2-diaminoethane,  $\text{O}_2\text{NN}(\text{CH}_3)\text{CH}_2\text{CH}_2\text{NHNO}_2$ ,  $\text{C}_3\text{H}_8\text{N}_4\text{O}_4$ , melts at 393–394 K (120–121 °C) and in the DTA the maximum of the exotherm peak is at 483 K (210 °C). *N,N'*-Dinitro-*N,N'*-dimethyl-1,2-diaminoethane,  $\text{O}_2\text{NN}(\text{CH}_3)\text{CH}_2\text{CH}_2\text{N}(\text{CH}_3)\text{NO}_2$ ,  $\text{C}_4\text{H}_{10}\text{N}_4\text{O}_4$ , melts at 409–410 K (136–137 °C) and in the DTA the maximum of the exotherm peak is at 558 K (285 °C), which is higher than that of EDNA or the monomethylEDNA [94]. The reaction of EDNA with ethylene dibromide produced *N,N'*-dinitropiperazine, a cyclic nitramine.

### 3.4 Linear Dinitramines with $\text{C}_{n \geq 2}$ Chains

*N*-Methyl-*N,N'*-dinitroethylenediamine, also known as 2,5-dinitrazapentane, *N*<sup>1</sup>-methyl-*N*<sup>1</sup>,*N*<sup>2</sup>-dinitro-1,2-ethanediamine, *N*-methyl-*N,N'*-dinitro-1,2-ethanediamine, MeEDNA,  $\text{H}_3\text{CN}(\text{NO}_2)\text{CH}_2\text{CH}_2\text{NHNO}_2$ ,  $\text{C}_3\text{H}_8\text{N}_4\text{O}_4$ , CAS RN [10308-90-4], is a methyl derivative of EDNA. The molecular weight of MeEDNA is 164.12 g/mol. The measured melting point is 393.6–394.9 K (120.5–121.8 °C). The predicted density is  $1.371 \pm 0.06 \text{ g/cm}^3$  at 293 K (20 °C). Like EDNA, MeEDNA is a relatively strong acid with a predicted  $\text{p}K_a$  of  $6.11 \pm 0.10$  at 298 K (25 °C).

2,4-Dinitro-2,4-diazapentane, also known as 2,4-dinitrazapentane, DNDA5,  $\text{H}_3\text{CN}(\text{NO}_2)\text{CH}_2\text{N}(\text{NO}_2)\text{CH}_3$ ,  $\text{C}_3\text{H}_8\text{N}_4\text{O}_4$ , CAS RN [13232-00-3], is an isomer of MeEDNA. 2,4-Dinitro-2,4-diazapentane melts at 328–330 K and the heat of fusion is 16.48 kJ/mol and its homologue 2,5-dinitro-2,5-diazahexane, dimethylethylenedinitramine, DMeEDNA,  $\text{H}_3\text{CN}(\text{NO}_2)\text{CH}_2\text{CH}_2\text{N}(\text{NO}_2)\text{CH}_3$ , melts at 408–410 K and the heat of fusion is 29.37 kJ/mol [40]. It can be synthesized from methylnitramine and dihalogenomethanes [97].

*N,N',N'',N'''*-tetranitro-1,1,2,2-ethanetetramine, *N*-(1,2,2-trinitramidoethyl)nitramide,  $\text{C}_2\text{H}_6\text{N}_8\text{O}_8$ , CAS RN [117080-06-5],  $M = 270.118 \text{ g/mol}$ , can form energetic salts with many organic bases [98].

*N*-(1,2,2-trinitramidoethyl)nitramide

The following DNDA compounds (dinitro-diaza-alkanes) have been evaluated as energetic plasticizers, not as pure compounds but as mixtures containing varying proportions of two or three of these compounds:

DNDA-5 *N,N'*-dimethylbis-nitramine, 2,4-dinitro-2,4-diazapentane

DNDA-6 *N*-methyl-*N'*-ethyl-bisnitramine, 2,4-dinitro-2,4-diazaheptane

DNDA-7 *N,N'*-diethylbisnitramine, 3,5-dinitro-3,5-diazaheptane

DNDAs can be prepared by nitration of *N,N'*-dimethylurea and *N,N'* diethylurea, hydrolysis of the dinitrodimethylurea and dinitrodiethylurea and condensation of the methyl- and ethylnitramine [99–101].

In another method for the synthesis of dinitro-diaza-alkanes from alkylamines and esters, a dialkyl ester of a dicarboxylic acid is reacted with a primary alkylamine to form the dialkyldiamide of the dicarboxylic acid. The dialkyldiamide is nitrated to form the dialkyldinitroamide of the dicarboxylic acid and the resulting dialkyldinitroamide is reacted with methylamine and/or ethylamine in an aqueous medium to yield a alkylnitroamine and the dimethyldiamide and/or diethyldiamide of the dicarboxylic acid, and the alkylnitramine needs to be isolated from that mixture [102].

The physical property data for several DNDA compounds are listed in Table 14. 3,5-Dinitrazaheptane,  $\text{H}_3\text{CCH}_2\text{N}(\text{NO}_2)\text{CH}_2\text{N}(\text{NO}_2)\text{CH}_2\text{CH}_3$ , DNDA-7, CAS RN [134273-34-0], a symmetrical molecule, is a constituent of DNDA-57.

Dinitrodiazaalkanes (DNDA-57) are mixtures of linear nitramine plasticizers and find use in low-temperature sensitivity coefficient propellants. DNDA-57 is a mixture of 2,4-dinitro-2,4-diazapentane (DNDA-5), 2,4-dinitro-2,4-diazaheptane (DNDA-6), and 3,5-dinitro-3,5-diazaheptane (DNDA-7) with varying percentage composition of  $40 \pm 5\%$ ,  $44 \pm 5\%$ , and  $11 \pm 2\%$ , respectively. A synthesis process of DNDA-57 was improved by slight modification of the reaction parameters to obtain good yield and the process was scaled up [103]. The mixture was thoroughly characterized by spectroscopic and thermal methods as well as GC/MS to determine the fragmentation pattern. It was found that the decomposition of DNDA-5, DNDA-6, and DNDA-7 follow identical patterns. DNDA-57 is relatively insensitive to friction and impact.

2,4-Dinitrazaheptane,  $\text{H}_3\text{CN}(\text{NO}_2)\text{CH}_2\text{N}(\text{NO}_2)\text{CH}_2\text{CH}_3$ , CAS RN [168983-72-0], DNDA-6, an asymmetric molecule, is an ingredient in a mixture of several nitramines called DNDA-57. The crystallization behavior of several dinitramines with plasticizing abilities in a nitrocellulose-(NC-)based gel was examined because the ability of these compounds to interact with NC is an important parameter for the development of double-base propellants [104, 105]. It was shown that, on the basis of their crystallization behavior, the nine studied dinitramines can be categorized into three

different groups. Whereas the first group (large symmetrical molecules) exhibited a strong crystallization tendency, the second group (asymmetric compounds) had low crystalline contents and showed a good interaction capacity with nitrocellulose. DNDA-6 (2,4-dinitro-2,4-diazahehexane) had the most pronounced interaction with nitrocellulose, due to its lowest content of crystalline plasticizer.

The energetic plasticizer mixture DNDA-57 as well as pure DNDA-6 resulted in promising propellant formulations having better ballistic properties as well as better cold elasticity [106]. The thermoanalytical properties of DNDA-5, DNDA-6, and DNDA-7 as well as of binary and ternary mixtures of these compounds were measured by TGA of the single components and cyclic DSC measurements of the pure components as well as of binary and ternary mixtures. Pure DNDA-6 had the lowest glass transition temperature of about 213 K ( $-60^{\circ}\text{C}$ ) (Onset  $T_g$ ) and the smallest melting enthalpy. Based on low  $T_g$  values, the use of DNDA-6 as a plasticizer should yield the best cold brittleness of new NC-propellant formulations. The onset-of-melting temperature of DNDA-6 ( $309\text{ K} = 36^{\circ}\text{C}$ ) was much above the lowest onset-of-melting temperature of the binary and ternary DNDA mixtures (about  $273\text{ K} = 0^{\circ}\text{C}$  for suitable mixtures of DNDA 5 DNDA-6 and for suitable ternary mixtures about  $269\text{ K} = -4^{\circ}\text{C}$ ).

## 4 Alkylnitramines with Explosophoric Substituents in the Alkyl Group

The energy content of dialkylnitramines can be increased by replacing terminal hydrogens in the hydrocarbon skeleton by energetic groups, such as nitroxy, nitro, nitramino, azido or difluoroamino groups. Of special interest are dialkylnitramines with two geminal nitro groups in the 2-position of the alkyl chains. Some of these nitroalkylnitramines are liquids and can be used as energetic plasticizers in double-base or composite propellants. Although in other sections of this book the nitroalkyl compounds are discussed ahead of the nitroxyalkyl compounds, the order has been reversed here because there is more to write about the nitroxyalkylnitramines than about the nitroalkylnitramines.

### 4.1 Nitroxyalkylnitramines (Nitratoalkylnitramines)

Nitroxyalkylnitramines can have one, two or more methylene groups between the nitroxy group and the nitramine group. The most common ones are those containing **two** methylene groups between the nitroxy group and the nitramine group, which are called nitroxyethylnitramines (NENAs). The nitroxy**ethyl**nitramines with different alkyl groups on the nitramine nitrogen will be discussed in a separate section in this chapter.

The effect of varying the number of methylene groups between the nitroxy group and the nitramine group on the thermal stability of nitroxyalkylnitramines was studied in the hope of obtaining plasticizers that are thermally more stable than *n*-butyl-*N*-(2-nitroxyethyl)nitramine (BuNENA).

Amino alcohol compounds such as propylamino propanol and ethylamino butanol are needed as precursors for production of energetic plasticizers similar to BuNENA. Straight chain aliphatic alkoxyalkylnitramines with three and four  $-\text{CH}_2-$  units between the nitrate ester and nitramine were synthesized in an effort to obtain plasticizers that are more stable than BuNENA which has two  $-\text{CH}_2-$  units [107]. However, unlike in BuNENA synthesis, various unwanted side reactions occurred in the nitration of amino alcohols. Fortunately, it was possible to considerably suppress the formation of side products in the nitration of propylamino propanol by using a solvent and an appropriate concentration of nitric acid. Other low-volatility nitroxyalkylnitramine compounds included 1,11-dinitrato-3,5,7,9-tetranitrazoundecane,

$\text{C}_7\text{H}_{14}\text{N}_{10}\text{O}_{14}$ , and 1,12-dinitrato-3,5,8,10-tetranitrazadodecane

$\text{C}_8\text{H}_{16}\text{N}_{10}\text{O}_{14}$  [108]. These high explosives were called TENA 1 and TENA 2, being **T**etranitramines as well as **N**ENA derivatives. Their synthesis from the alkyl chlorides with silver nitrate is rather expensive.

The heats of explosion  $Q_{\text{ex}}$  of six linear dinitramines (DNDA5, DNDA6, DNDA7, EDNA, M-EDNA, and DM-EDNA), three dinitramines with azido groups (DN3, AZD6, and BAED), and six nitrateethylnitramines (DINA, MeNENA, EtNENA, BuNENA, BNE-MEDINA, and BNE-EDNA) were determined by combustion in a calorimeter bomb, sometimes in mixtures with nitrocellulose (NC) [109]. It was noted that for some substances the determination did not result in constant  $Q_{\text{ex}}$  values, which questioned the general applicability of the method. In order to explain this nonlinear behavior, a detailed investigation was started. Constant  $Q_{\text{ex}}$  values lying over 4000 J/g with a small deviation were obtained for compounds with an oxygen balance above  $-60\%$ , whereas in the range of  $-60$  to  $-70\%$  the  $Q_{\text{ex}}$  values between 3400 and 3700 J/g presented pronounced deviations. For compounds with an oxygen balance below  $-70\%$ , the calculated  $Q_{\text{ex}}$  value increased strongly with rising percentages of the compounds in mixtures with NC. Neither the type of explosophoric groups such as  $-\text{NNO}_2$ ,  $-\text{ONO}_2$ , or  $-\text{N}_3$  nor the nitrogen content or the type of energetic additive (RDX or NC) in the analyzed mixtures had any decisive effect on the  $Q_{\text{ex}}$  deviations. 1-Nitroxy-3-nitrazapentane or 1-nitroxy-3-nitrazabutane in mixtures with 2-azidoethanol or 1,3-diazidopropanol can be used as monopropellants [110].

#### 4.1.1 Thermal Stability of Nitroxyalkylnitramines

The thermal decomposition behavior of several energetic plasticizers including 58.8/41.2 mass-% *N*-methyl-*N*-ethyl-NENA (NENA = 2-nitratoethylnitramine) and DANPE (1,5-diazido-3-nitrazapentane) and uncured binders was investigated in 10 mass-% solutions in toluene by adiabatic self heating in an accelerating rate calorimeter (ARC) [111]. The closed ARC system prevented the solutions from evaporating and maintained adiabatic conditions. The cells with a diameter of 1 in. were made from titanium. All undiluted energetic substances would deflagrate destructively after a short period of controllable self heating. The advantage of the investigation of solutions was that the decomposition of the energetic substances could be followed in a fully controlled way. With the self-heat rate curves, one can characterize the plasticizers and binders with respect to the decomposition temperature range, the heat quantity, and the heat generation rate. The Arrhenius parameters and the released heats of reaction were then determined from the self heat rate curves, which were typically reactions of first order. A secondary reaction was found in the case of the ARC trace of a 10% solution of Me/Et-NENA in toluene (Figure 4). Presumably, the second reaction is the decomposition of the nitramine group in connection with the residual part of the already decomposed nitric acid ester group. The onset temperature of decomposition was 403 K (130 °C) for Me/Et-NENA. The activation energy was  $165.1 \pm 0.4 \text{ kJ/mol}$  and the pre-exponential factor was  $1.449 \times 10^{16} \text{ s}^{-1}$ . Me/Et-NENA had the lowest onset temperature of several energetic plasticizers and binders tested. At an extrapolated temperature of 358 K (85 °C) the

**Figure 4:** Decomposition ARC thermogram of 10% *N*-methylNENA/ 90% *N*-ethylNENA mixture. (Republished and modified from [111], with permission of ©1999 Elsevier Science & Technology Journals; permission conveyed through RightsLink.)

measurable heat generation rate in the ARC would be  $25\mu\text{W/g}$ . DANPE also had a relatively low extrapolated  $25\mu\text{W/g}$  temperature of  $379.2\text{K}$  ( $106.1^\circ\text{C}$ ) while glycidyl azide polymer (GAP) started at about  $387\text{K}$  ( $114^\circ\text{C}$ ).

## 4.2 Nitroxyethylnitramines

The nitroxyethylnitramine (nitratoethylnitramine) family compounds (NENAs) are effective plasticizers in energetic formulations, particularly in nitrocellulosic systems. NENAs contain both nitrate ester and nitramine functionalities, and have the following structure:

where R can be a methyl, ethyl, propyl, isopropyl, butyl, or pentyl group. The structurally related 1,5-diazido-3-nitrazapentane, or DANPE, is discussed here following the alkyl-NENAs. The NENAs have been known since the 1940s, when DINA (dinitroxyethyl nitramine) was scaled-up for use in Navy flashless gun propellants. It was not until the late 1970s that researchers at Eglin AFB began to use NENAs in gun propellants that required low flame temperatures and low molecular weight [112].

NENAs are readily manufactured by nitration of commercially available alkyl ethanolamines, in good yields (80%):

Sometimes mixtures of nitroxylalkylnitramines give better results in double-base propellants than the pure compounds by themselves. Mixtures of nitroxylalkylnitramines are liquids at room temperature, while the pure compounds may be solids. Instead of mixing separately prepared DINA and alkylNENA, mixtures of the hydroxyalkylamine precursors can be co-nitrated [113, 114].

The use of NENAs as plasticizers in gun and rocket propellants allows the production of propellants with excellent properties such as high burning rates, reductions in flame temperature and product gas molecular weight, and higher specific impulse (based on moderate loadings of 60–70% RDX in a nitrocellulose/NENA binder, also containing nitroguanidine) [115–117].

Heats of combustion of NENA plasticizers and associated azido derivatives can be calculated by a simple yet reliable and accurate method [112]. Heats of formation (Table 6) can then be derived from the heats of combustion and used to calculate a wide range of gun propellant performance.

Not only do NENA compounds promise low combustion gas molecular weight products, but this characteristic (in combination with conventional ingredients) makes higher energy levels possible. Derivatives of NENAs carrying azido groups in place of nitrato groups promise even greater potential due to their positive heats of formation.

**Table 6:** Properties of condensed phase alkylNENAs.

|                                    |          | MeNENA | EtNENA | PrNENA | BuNENA | PentyINENA |

Data source: [112]

The application of NENAs as energetic plasticizers in specific solid propellant formulations will be described in a future volume on solid propellants. Here we discuss only the preparation, physical, chemical, and safety properties of the pure compounds. NENAs possess good thermal stability, they readily plasticize nitrocellulose, and other polymers, generate low molecular weight combustion gases, and have low impact sensitivity [118]. Additional important properties are listed in Table 7, but the enthalpy of formation numbers shown here exactly as copied from the source are obviously wrong because these numbers for the liquid compounds should all be negative, which also applies to the numbers reported by other investigators. Apparently these data were derived from heats of combustion and either the upper or the lower heat of combustion was used.

**Table 7:** Properties of condensed phase alkylNENAs.

Data source: [119] as quoted from Simmons [118]

The molecular structures of nitroethylnitramine (NENA), its tautomers, and its charged forms were calculated quantum chemically, using various basis sets at the levels of *ab initio*, and density functional theories (DFT) [120]. NENA may be sensitive to negative charge development, resulting in rupture of the —O—NO<sub>2</sub> bond. Conformational and molecular dynamics studies gave predicted geometrical parameters,

energies, and IR spectra. Calculations indicated that the *s-cis* conformation of NENA should be slightly more stable than the *s-trans* conformation. The tautomers have very comparable total energy values to NENA. On the other hand, on the basis of homolytic bond dissociation energies (BDE) for  $\text{—O—NO}_2$  bonds in the structures, it was proposed that the presence of the tautomers in the bulk of NENA should somewhat decrease its sensitivity.

The volatility of three 2-nitroxyethylnitramine (NENA) compounds in an NC-based double-base propellant was compared to those of diethylene glycol dinitrate (DEGDN), and nitroglycerin (NG) using TGA at constant temperature at three different temperatures [121]. Initial concentration of plasticizer and degree of nitration of NC were also varied. The NENA plasticizers had lower vaporization rates than DEGDN or NG.

Alkylsulfamates react with ethylene oxide to form *N*-ethanolsulfamates, and *N*-di(ethanol)sulfamates which can be nitrated to form energetic nitroxyalkyl-nitramines. As a result of nitration, a quaternary nitramine mixture (QNM) was obtained in 60–70% yield [122]. The QNM consisted of 2,4-dinitro-2,4-diazapentane (I), 1-nitroxy-3,5-dinitro-3,5-diazaheptane (II), 1,7-dinitroxy-3,5-dinitro-3,5-diazaheptane (III), and 1,5-dinitroxy-3-nitro-3-azapentane (IV).

The QNM is a low-melting substance with a melting point from 291 to 323 K, depending on ratio of the components, and an enthalpy of formation of  $\Delta H_f = -813 \text{ kJ/kg}$ . The ratio of components I, II and III in the QNM was determined from the ratio of the  $^1\text{H}$  NMR signals of the methylene protons between the nitramine groups  $\text{—N(NO}_2\text{)CH}_2\text{N(NO}_2\text{)}$  and of the methylene group adjacent to the nitramine group of the ethyl nitrate moiety  $\text{—N(NO}_2\text{)CH}_2\text{ONO}_2$ . Azidation of the QNM in a DMF yielded a quaternary azide mixture (QAM) consisting of 2,4-dinitro-2,4-diazapentane (I), 1-azido-3,5-dinitro-3,5-diazaheptane, 1,7-diazido-3,5-dinitro-3,5-diazaheptane, and 1,5-diazido-3-nitro-3-azapentane.

The ideal gas phase thermochemical properties of ethyl-2-mitrato-1-nitramine (NENA) and its family of alkyl substituted compounds methyl-, ethyl-, propyl-, butyl-, and pentyl-NENA were calculated and presented in NASA-type polynomial format that can be used for rocket performance calculations [123]. See also [124].

### 4.3 2-Nitroxyethylnitramine, NENA

The simplest nitramine in this group is 2-nitroxyethylnitramine, NENA,  $\text{O}_2\text{NOCH}_2\text{CH}_2\text{NHNO}_2$ . This compound and its alkylated homologues can be synthesized by first forming the nitrate salts of hydroxyalkylamines, followed by nitration in acetic anhydride [2, 125].

NENA is a liquid at room temperature but freezes at 288 K (15 °C). The oxygen balance of NENA is  $-15.9\%$ . It is thermally stable up to 573 K (300 °C) and volatile at that temperature. The impact sensitivity (50% point) of NENA reported from two different sources is 191 or 107 cm. The hydrogen on the nitrogen adjacent to the *N*-nitro group is acidic and this compound forms ammonium and silver salts. The pH of a NENA solution in water is 2.7. In the lead block test, the power of NENA was 134% that of TNT.

### 4.4 Methyl-2-nitroxyethylnitramine, MethylNENA

The first NENA homologue is 2-nitroxyethyl methyl nitramine, also known as 2-(methylnitroamino)ethyl nitrate, 2-[methyl(nitro)amino]ethyl nitrate, methyl-NENA, methylNENA, MeNENA,  $\text{C}_3\text{H}_7\text{N}_3\text{O}_5$ , CAS RN [17096-47-8],  $M = 165.105 \text{ g/mol}$ .

MethylNENA

MeNENA is the simplest of the alkylated NENA compounds, with other notable members in this family being Et- and *n*-BuNENA. MethylNENA is a solid at room temperature and melts at 311–313 K (38–40 °C). It is thermally stable up to 573 K (300 °C). The impact sensitivity is more than 90 cm (RDX for comparison: 48–50 cm). The density of the liquid is  $1.40 \text{ g/cm}^3$  and the density of the solid at 298 K = 25 °C is  $1.53 \text{ g/cm}^3$ . The properties of methylNENA are summarized in Table 8.

It was attempted to lower the melting point of MeNENA by mixing it with other nitramines [2]. It is soluble in acetic acid and can be recrystallized from solutions in acetic acid.

The energetic plasticizer *N*-methyl-*N*-(2-nitroxyethyl)nitramine and its precursor *N*-methyl-*N*-(2-nitroxyethyl)ammonium nitrate were synthesized by nitration of 2-(methylamino)ethanol and characterized by XRD, multinuclear NMR spectroscopy ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ), vibrational spectroscopy (IR and Raman), mass spectrometry, and DTA [127]. For the synthesis of *N*-methyl-*N*-(2-nitroxyethyl)nitramine, a colorless

<sup>a</sup> As referenced in NIST Chem WebBook [85]

crystalline solid, the commercially available 2-(methylamino)ethanol can be nitrated in a mixture of pure nitric acid and acetic anhydride in the presence of zinc chloride as catalyst. The intermediate *N*-methyl-*N*-(2-nitroxyethyl)ammonium nitrate can be isolated as a colorless, fine crystalline solid upon mixing of the reaction mixture with diethyl ether. The crystal structure parameters of *N*-methyl-*N*-(2-nitroxyethyl)ammonium nitrate and *N*-methyl-*N*-(2-nitroxyethyl)nitramine at 173 K are summarized in Table 9.

MeNENA showed three signals in its <sup>1</sup>H NMR spectrum. The methyl group C3 exhibited a singlet signal at 3.47 ppm, whereas the two methylene groups showed multiplet signals at 4.27 (C2) and 4.87 ppm (C1). The <sup>13</sup>C{<sup>1</sup>H} NMR spectrum also showed three signals, with C3 having a shift of 39.9 ppm, C2 being at 50.7 ppm, and C1 having a downfield shift of 70.8 ppm. The <sup>14</sup>N NMR spectrum exhibited two signals: one for the nitroxy group at -38 ppm and one for the nitro group at -23 ppm. The DTA thermogram (Figure 5) showed a *N*-methyl-*N*-(2-nitroxyethyl)ammonium nitrate melting point with an onset at 346 K (73 °C) and a decomposition starting at 407 K (134 °C). For comparison, the parent acid, MeNENA began to melt at 304 K (31 °C) and began to decompose at 453 K (180 °C).

The theoretical detonation velocity of MeNENA was predicted to be 8050 m/s in comparison to that of RDX which was predicted to be 8748 m/s.

#### 4.5 Ethyl-2-nitroxyethylnitramine, EthylNENA

The next homologous member of the group of nitramines is 2-nitroxyethyl ethyl nitramine, also known as 2-(ethylnitroamino)ethyl nitrate, 2-(ethylnitroamino)-ethanol 1-nitrate, O<sub>2</sub>NO—CH<sub>2</sub>—CH<sub>2</sub>—N(NO<sub>2</sub>)—CH<sub>2</sub>—CH<sub>3</sub>, C<sub>4</sub>H<sub>9</sub>N<sub>3</sub>O<sub>5</sub>, ethyl-NENA,

ethylNENA, EtNENA, CAS RN [85068-73-1], which is a yellow oil at room temperature and freezes at 277–278.5 K (4–5.5 °C). The properties of ethylNENA are summarized in Table 10. MEN-42 is a eutectic mixture of methyl- and ethyl-NENA.

#### 4.6 *n*-Propyl-2-nitroxyethylnitramine, ProNENA

*n*-Propyl-2-nitratoethylnitramine, also known as *n*-propyl-2-nitroxyethylnitramine, 2-nitropropylaminoethanol nitrate ester, ProNENA, O<sub>2</sub>NO—CH<sub>2</sub>—CH<sub>2</sub>—N(NO<sub>2</sub>)—CH<sub>2</sub>—CH<sub>2</sub>—CH<sub>3</sub>, C<sub>5</sub>H<sub>11</sub>N<sub>3</sub>O<sub>5</sub>, CAS RN [82486-83-7] is less well characterized than the other three NENAs. It can be used as a plasticizer in double-base propellants. The physical properties of *n*-ProNENA are summarized in Table 11.

#### 4.7 *n*-Butyl-2-nitroxyethylnitramine, BuNENA

Another member of the group of nitramines is 2-nitroxyethyl *n*-butyl nitramine, also known as *n*-butyl-*N*-(2-nitroxyethyl)nitramine, *n*-butyl-nitratoethyl-nitramine, *N*-*n*-butyl-*N*-(2-nitroxyethyl)nitramine, 2-(butylnitroamino)ethanol nitrate, 2-[butyl(nitro-amino)ethyl nitrate, O<sub>2</sub>NO—CH<sub>2</sub>—CH<sub>2</sub>—N(NO<sub>2</sub>)—CH<sub>2</sub>—CH<sub>2</sub>—CH<sub>2</sub>—CH<sub>3</sub>, C<sub>6</sub>H<sub>13</sub>N<sub>3</sub>O<sub>5</sub>, butyl-NENA, butylNENA, BuNENA, CAS RN [82486-82-6], *M* = 207.184 g/mol, which is a yellow oil that freezes at 263.2 K (–9.9 °C). *n*-Butyl-2-nitroxyethylnitramine is

**Table 11:** Physical properties of *n*-propylNENA.

a combination of a nitrate ester and a nitramine, carrying two types of explosophoric groups in the molecule:

ButylNENA

BuNENA can be used as an energetic plasticizer in double-base propellants. In the pure state, BuNENA is a colorless oily liquid with a density of 1.21 g/cm<sup>3</sup> and a freezing point of 264 K = −9 °C. Practical grades may have the appearance of a yellow oily liquid.

#### 4.7.1 Preparation of *n*-ButylNENA

*n*-Butyl-2-nitroxyethylnitramine can be prepared from *n*-butylethanolamine and nitric acid with acetic anhydride and a chloride source for catalysis. *n*-BuNENA is an energetic plasticizer for solid propellant formulations. The laboratory synthesis of *n*-BuNENA was scaled up to the 1 kg batch size and the compound was fully characterized by spectral data and elemental analysis [129]. *n*-BuNENA was formulated with composite modified double-base (CMDB) and extruded double-base (EDB) propellant compositions. The results showed an improvement in mechanical properties and burning rate over a wide range of pressure along with acceptable limits of hazard and thermal stability as compared to diethyl phthalate-plasticized propellant systems.

It was attempted to gain some insight into the BuNENA synthesis pathway. Step 1 involved *N*-butyl-ethanolamine addition to 98% HNO<sub>3</sub> to form a salt mixture; step 2 was addition of acetic anhydride/acetyl chloride catalyst to the salt mixture. A number of potential intermediates, by-products, and decomposition products from this pro-

cess were identified/synthesized for use as analytical standards [130]. Potential intermediates and by-products formed during BuNENABuNENA synthesis were identified. These included nitrate salts, acetate ester, nitramine alcohol, and a free nitrate ester. The rate of consumption of acetyl nitrate was measured in order to limit its accumulation in the reaction vessel, which would be an operational hazard.

*N*-Methyl-*N*-(2-nitroxyethyl)nitramine (MeNENA), *N*-ethyl-*N*-(2-nitroxyethyl)nitramine (EtNENA), and *n*-butyl-*N*-(2-nitroxyethyl)nitramine (BuNENA) were prepared by the reactions of methylethanolamine, ethylethanolamine, or butylethanolamine and nitric acid with acetic anhydride, respectively [131]. The structures of the NENAs were identified by  $^1\text{H}$  NMR, IR, and elemental analysis. The parameters affecting the yield and purity of EtNENA, such as temperature, reaction time, nitric acid, and acetic anhydride were optimized. The optimum conditions were given: mol ratio of (ethyl ethanolamine):(nitric acid):(acetic anhydride) = 1:2.6:2.4, the reaction temperature of the first stage 278–283 K (5–10 °C), the reaction temperature of the second stage 313–318 K (40–45 °C), reaction time 15 min. Under these conditions, the yield of EtNENA was over 84% and the purity of the refined product was greater than 98%. The physical, chemical, and safety properties and thermal decomposition of alkyl-NENAs were also measured.

#### 4.7.2 Physical Properties of *n*-ButylNENA

Some physical properties of BuNENA were already included in Table 7. The physical properties of *n*-BuNENA are summarized in Table 12.

It is unclear why someone would want to dissolve BuNENA in DMSO, but apparently there must be an application for this. The densities and viscosities of binary liquid mixtures of BuNENA with DMSO were measured at 298, 313, 323, and 343 K (25, 40, 50, and 70 °C) by using a pycnometer and an Ubbelohde-type capillary viscometer [134]. The experimental data of viscosities, temperature, and composition were fitted to theoretical relations. The average relative error of calculated data was between 0.17 and 1.53%.

#### 4.7.3 Chemical Properties of *n*-Butyl-NENA

BuNENA is a weak acid. Its predicted  $\text{p}K_{\text{a}}$  is  $-8.52 \pm 0.70$ .

##### 4.7.3.1 Reactions of *n*-Butyl-NENA

One disadvantage of NENA plasticizers is a potential incompatibility with AP. Such AP and nitrate esters compatibility issues have often been resolved by the inclusion of free radical scavengers (2-nitrodiphenylamine or alkaline additives such as sodium bicarbonate). Neither have proved effective for NENAs. Alkylureas were considered as stabilizers for NENAs when used in combination with AP [135].

**Table 12:** Physical properties of *n*-butylNENA.

A semiempirical molecular orbital theory method was used to study the interaction of BuNENA with polyethylene glycol (PEG), HTPB, GAP, poly(3-azidomethyl)-3-methyl-oxetane or poly(3,3-bis(azidomethyl)-oxetane) binders in solid propellants [136]. Binding energies were only approximately obtained. Except in the case of BuNENA with PEG, the strength of the intermolecular interaction of complex systems decreased with decreasing degree of polymerization.

#### 4.7.3.2 Decomposition of *n*-Butyl-NENA

Thermal stability and compatibility in terms of DSC compatibilities and vacuum stabilities for pure methyl-, ethyl-, and butyl-NENAs and DINa, as well as mixtures of these and testing results with mixtures of these with several propellant ingredients including RDX, AN, and polyNIMMO were compared to those of standard nitrate ester plasticizers [115]. Specific comparisons were made to BDNPA/F, butanetriol trinitrate (BTTN), and methyltrimethylolmethane trinitrate (TMETN). As with vacuum stability results, it was shown that performance parameters are very favorable with regard to other ingredients.

Thermal stability studies of combinations of NENA/AP mixtures and various stabilizing ingredients using DSC in both isothermal and scanning modes, vacuum stability as well as stability at atmospheric pressure have led to a better understanding

of the reactions between AP and NENAs as well as the discovery of novel stabilizing materials that could be used with these mixtures. Surprisingly, nitroguanidine was established as an especially good stabilizer [116, 137]. Comparisons were made between nitroguanidine (NQ) and commonly used stabilizing ingredients such as 2-nitrodiphenylamine (2-NDPA) and ethylcentralite.

BuNENA, having nitramine and nitrate ester moieties in the molecule, is prone to autocatalytic decomposition. A stability analysis has indicated that it is a moderately stable compound and does not require additional stabilizer [138]. The stability and sensitivity of *n*-BuNENA as compared with GTN is much higher, but like all nitrate esters, it suffers from inherent instability due to the low O–NO<sub>2</sub> bond energy. The decomposition is accompanied by moderate heat generation and gas production. It is also accelerated by the presence of moisture. The decomposition reaction is a hydrolysis which leads to the formation of *n*-butyl-ethanolnitramine (Bu-ENA) and nitric acid. Stability of BuNENA can be measured by the Bu-ENA formation rate and by microcalorimetry. The stability of high quality material is good enough that a stabilizer is not necessarily needed. As the main reaction is initiated by hydrolysis, it is recommended that BuNENA is stored in dry conditions. Surprisingly, DSC did not differentiate very well between stable and unstable samples. The main difference is found in the peak areas, not in the onset or peak maximum temperatures. The interim decomposition product Bu-ENA is still an energetic material with an exothermic decomposition behavior.

#### 4.7.3.3 Analysis of *n*-Butyl-NENA

The purity requirements for BuNENA are documented in the European specification STANAG 4583.

#### 4.7.3.4 Applications of *n*-Butyl-NENA

Applications of BuNENA as a plasticizer for CMDB and composite propellants will be discussed in detail in future sets on solid propellants. In this section, references to some publications on BuNENA and similar nitramine plasticizers and their potential applications are provided.

The development history and contemporary status of nitroxyethylnitramines (NENAs) and properties of propellants and explosives containing NENAs as plasticizers and their possible applications have been reviewed [139].

Gun propellant compositions containing BuNENA as an energetic plasticizer with varying percentage of RDX have been studied theoretically and experimentally [140]. Experimental data indicated that BuNENA based propellants are superior to dioctyl phthalate plasticized propellants with respect to ballistic performance.

BuNENA is an energetic plasticizer with excellent performance. In gun propellants, BuNENA has the advantages of high plasticizing ability, good process performance, low sensitivity, high energy, and it can improve the mechanical properties of

the formulations [141]. For instance, in HTPE-bonded (hydroxyl-terminated ethylene oxide-tetrahydrofuran block co-polyether) rocket propellant, BuNENA increased energy, decreased sensitivity, and improved mechanical properties of the propellant.

#### 4.8 Di(nitroxyethyl)nitramine, DINA

If both terminal C-atoms in diethylnitramine carry a hydroxyl group and both hydroxyl groups are esterized with nitric acid, one obtains a very energetic nitramine, 1,5-dinitroxy-3-nitrazapentane, also known as 1,5-dinitrato-3-nitrazapentane,  $\beta,\beta$ -dinitroxydiethylnitramine, DINA, di(nitroxyethyl)nitramine, diethanoldinitrate nitroamine, dioxyethylnitramine dinitrate, dihydroxyethylnitramine dinitrate, di-2-hydroxyethylnitramine dinitrate, 1,5-dinitrato-3-nitrazapentane, diethanolnitramine dinitrate; ethanol 2,2'-nitroiminodinitrate; ethanol, 2,2'-(nitroimino)di-, dinitrate (ester); 2,2'-dinitroxydiethylnitramine, dinitrate ester of di(2-hydroxyethyl)nitramine, dihydroxyethylnitramine dinitrate, 2-[nitro(2-nitrooxyethyl)amino]ethyl nitrate, (nitroimino)di-2,1-ethanediyl dinitrate,  $\text{O}_2\text{NO}-\text{CH}_2-\text{CH}_2-\text{N}(\text{NO}_2)-\text{CH}_2-\text{CH}_2-\text{ONO}_2$ ,  $\text{C}_4\text{H}_8\text{N}_4\text{O}_8$ , CAS RN [4185-47-1],  $M = 240.128$  g/mol. The molecule is slightly underoxidized with an oxygen balance of -26.6%. DINA is a combination of a nitrate ester and a nitramine, carrying two types of explosives groups in the same molecule:

Di(nitroxyethyl)nitramine

##### 4.8.1 Preparation of DINA

DINA can be prepared from diethanolamine and nitric acid with acetic anhydride as a dehydrating agent and in the presence of hydrochloric acid as a catalyst [142]. The nitration product is stabilized by boiling in water to remove partially nitrated intermediates (nitrosamine), followed by dissolution in acetone and reprecipitation with water. The product is recrystallized from acetone by precipitating it with water. DINA forms colorless crystals and is insoluble in water.

##### 4.8.2 Physical Properties of DINA

Nobody would want to heat DINA to the boiling point, but if it is done (by remote control), the boiling point is 475 K (202°C = 396°F). Several other properties of DINA

**Table 13:** Properties of 1,5-dinitroxy-3-nitrazapentane (DINA).

| Property                       | SI units                       | Other units                 | References |

are summarized in Table 13. Double-base propellants plasticized with DINA instead of nitroglycerin are named “Albanite.”

### 4.8.3 Chemical Properties of DINA

DINA is a weak acid. The acid constant  $pK_a$  was predicted to be  $-10.40 \pm 0.70$  at 298 K.

#### 4.8.3.1 Thermal Stability of DINA

The thermal decomposition of DINA was examined to determine whether the N–NO<sub>2</sub> linkage or the C–O–NO<sub>2</sub> linkage is the first to break. When examining the critical conditions of thermal explosions of DINA, there was good agreement of the experimental values of temperatures and heat evolution with calculated values from Semenov’s theory [34, 144].

The kinetics of the thermal decomposition of diethylnitramine dinitrate were studied by three different methods: by gas liberation, by the change in weight, and by heat evolution [145]. The reaction is first order and the rate constant, activation energy, and pre-exponent were calculated.

#### 4.8.4 Strand Burning of DINA

The combustion stability of DINA [2,2'-(nitroimino)diethanol dinitrate] was determined in a manometric bomb calorimeter and the effect of initial temperature on the combustion stability was also determined [146]. The presence of a molten layer on the surface of the explosive had no effect on the combustion stability. However, whether normal or accelerating combustion, or even explosion, occurred depended upon the charge density. Combustion stability decreased as the density decreased. The initial temperature had no effect on the combustion stability of DINA. Its combustion stability depended mainly upon the charge density.

The strand burning of DINA cast into 0.9-cm diameter  $\times$  3 cm height beakers was measured in a constant pressure bomb [147]. At an initial temperature of 293 K (20 °C) and 1–100 bar pressure, the burning velocity of sym-dinitroxydiethylnitramine can be described by the equation

$$v = (0.03 + 0.008P)$$

where  $v$  is the burning rate in cm/s and  $P$  is the pressure in bar. At elevated starting temperatures, at the initial conditions of 328 K (55 °C) and 5–25 bar pressure, the burning rate of the molten, liquid compound can be described in accordance with the equation

$$v = (0.045 + 0.0125P)$$

where  $v$  is the burning rate in cm/s and  $P$  is the pressure in bar. The temperature coefficient was virtually independent of pressure. At the initial conditions of 293 K (20 °C) and 8 bar and higher, formation of a bright white flame was noticed at a certain distance from the surface of the liquid top layer of the sample. With increasing pressure, this distance decreased and at  $p = 25$  bar the bright flame touched the surface of the sample. The dependence of the distance between the lower edge of the flame and the surface of the condensed phase of the compound was described by the equation:

$$L = \frac{700}{P^{2.5}}$$

where  $L$  is the distance in cm and  $P$  is the pressure in bar.

The effects of  $K_2CrO_4$ ,  $K_2Cr_2O_7$ ,  $(NH_4)_2Cr_2O_7$ , graphite, and mixtures of graphite with lead and copper salts on the burning rate of DINA were examined by visual observation in a combustion bomb [148]. Surface effects were predominant with graphite additives, especially with ternary mixtures of graphite with lead and copper salts. The

active component of the chromium compounds appeared to be an amorphous oxide of Cr formed at 593–603 K (320–330 °C). The most effective of the additives studied was  $(\text{NH}_4)_2\text{Cr}_2\text{O}_7$ , possibly due to the high temperature and infrared radiation of the incandescent particles resulting in a burning velocity of 0.5 mm/s.

The strand burning rate of DINA was measured in 6- to 32-mm glass tubes with 1-mm walls at atmospheric pressure [149]. Combustion rates in relation to the diameter of the DINA specimens were studied. Steady-state flame propagation was possible only in tubes which were >13 mm in diameter. Between 15 and 32 mm, the burning rate was independent of tube diameter and remained at 0.135 mm/s.

The burning rate of DINA at atmospheric pressure was shown to be determined by the rate of heat evolution in the reaction zone of the condensed phase as well as by the heat flux radiated from the gas phase [150]. The effects of two groups of additives on the strand burning rate of DINA were examined, including ammonium persulfate, hydrazinium sulfate, and hydroxylammonium sulfate, which increased the burning rate through the intensification of heat evolution in the condensed phase, and also soot and compounds of hexavalent chromium, lead, and copper, which accelerated burning as a result of additional heat flux from incandescent condensed particles formed on the burning surface.

The effect of adding 2.6–4%  $(\text{NH}_4)_2\text{Cr}_2\text{O}_7$ ,  $\text{K}_2\text{Cr}_2\text{O}_7$ , or  $\text{K}_2\text{CrO}_4$  on the burning mechanism of DINA and DINA containing 2% glycerol trinitrate (GTN) was investigated in a combustion bomb [151].

The strand burning rate of DINA with and without catalysts was measured in 18-mm glass tubes at atmospheric pressure or 7-mm quartz tubes for experiments at elevated pressures [152]. The strand burning rate of uncatalyzed DINA at atmospheric pressure was 0.08 mm/s. The catalysts, PbO,  $(\text{CH}_3\text{COO})_2\text{Cu}$ , and carbon black had a significant effect on the burning rate. A mixture of 5.5%  $(\text{CH}_3\text{COO})_2\text{Cu}$  and 1.5% PbO increased the burning rate to 0.15 mm/s and a mixture of 3%  $(\text{CH}_3\text{COO})_2\text{Cu}$ , 1.5% PbO and 1% carbon black increased the burning rate to 0.45 mm/s.

The effects of the addition of 5%  $(\text{NH}_4)_2\text{S}_2\text{O}_8$ ,  $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{SO}_4$ , or  $\text{NH}_2\text{OH} \cdot 0.5\text{H}_2\text{SO}_4$  on the combustion velocity of DINA in the condensed phase were also investigated [153]. The additives lowered the temperature of the beginning of exothermic decomposition of DINA to 453–463 K (180–190 °C) and increased the summary heat effect of its thermal decomposition to almost twice as much as without additives  $\leq 879$ – $962$  J/g ( $\leq 210$ – $230$  cal/g). The additives increased the burning velocity of DINA and changed its burning properties in the condensed phase.

The combustion of DINA was studied at atmospheric pressure with and without catalytic additives [154]. The strand burning rate is determined by the rate of heat evolution in the reaction zone of the condensed phase as well as by the heat flux from the flame in the gas phase. Two groups of additives were examined: (1) compounds such as  $(\text{NH}_4)_2\text{S}_2\text{O}_8$ , hydrazinium(2+) sulfate, and hydroxylammonium sulfate, which increase the burning rate by way of an intensification of heat evolution in the condensed phase, and (2) compounds of hexavalent chromium and composite additives,

including carbon soot, and lead and copper salts which accelerate burning as a result of additional heat flux from incandescent condensed particles formed on the burning surface and heated to 1273–1473 K (1000–1200 °C) by the heat from heterogeneous catalytic reactions. In the case of the chromium compounds, the active ingredient responsible for the catalytic effect is  $\text{Cr}_2\text{O}_3$  formed in a combustion front.

#### 4.8.5 Safety Properties of DINA

In a U-tube adiabatic compression sensitivity test apparatus with variable, preselected push pressure and constant bubble size, DINA and BuNENA were less sensitive than GTN, DEGDN, or EGDN [155].

#### 4.8.6 Explosive Performance of DINA

The volume of explosion gases of DINA is 924 L/kg and the heat of explosion is 5458 kJ/kg = 1304 kcal/kg for combustion to liquid water and 5025 kJ/kg = 1201 kcal/kg for combustion to steam. The detonation velocity of a confined charge is 7580 m/s = 25000 ft/s at  $\rho = 1.47 \text{ g/cm}^3$ . The impact sensitivity is 0.6 kpm = 6 Nm in the BAM tester.

#### 4.8.7 Applications of DINA

DINA is an energetic plasticizer for double-base propellants. DINA has been used as a gelatinizer for nitrocellulose and is a powerful explosive in its own right, comparable to RDX and PETN. Double-base propellants based on DINA instead of glycerol trinitrate were named “Albanite” because of the white color of the mixture.

An energetic plasticizer mixture based on 1,5-dinitrato-3-nitrazapentane (DINA) and 1,5-diazido-3-nitrazapentane had a eutectic freezing point below 248 K (–25 °C). When this eutectic mixture was combined in a propellant composition along with HMX, GAP, and AP, it resulted in propellants equivalent to GTN-based systems but with improved storability.

## 5 Linear Nitratoalkyl Nitramines with Two or More Nitramine Groups

1,7-Dinitroxy-3,5-dinitrazaheptane, 2,2'-bis-[methylenebis(nitroimino)]ethanol 1,1'-dinitrate, 2-[nitro-[nitro(2-nitrooxyethyl)amino]methyl]amino]ethyl nitrate,  $\text{C}_5\text{H}_{10}\text{N}_6\text{O}_{10}$ ,  $\text{O}_3\text{NCH}_2\text{CH}_2\text{N}(\text{NO}_2)\text{CH}_2\text{N}(\text{NO}_2)\text{CH}_2\text{CH}_2\text{NO}_3$ , CAS RN [71545-64-7], is a symmetrical molecule and a nitramine with a higher molecular weight and lower vapor pressure than some of the other NENAs which are also used as plasticizers.

1,7-Dinitroxy-3,5-dinitrazaheptane

1,7-Dinitroxy-3,5-dinitrazaheptane has a molecular mass of 314.17 g/mol, melts at 365–366 K (92–93 °C), and has a predicted density of  $1.658 \pm 0.06 \text{ g/cm}^3$  at 293 K (20 °C).

Its homologue, 1,8-dinitroxy-3,6-dinitrazaoctane, 1,8-dinitrato-3,6-dinitrazaoctane, 1,8-dinitrato-*N,N'*-dinitro-3,6-diazaoctane, 2-[nitro-[2-[nitro(2-nitrooxyethyl)-amino]ethyl]amino]ethyl nitrate,  $\text{O}_3\text{NCH}_2\text{CH}_2\text{N}(\text{NO}_2)\text{CH}_2\text{CH}_2\text{N}(\text{NO}_2)\text{CH}_2\text{CH}_2\text{NO}_3$ ,  $\text{C}_6\text{H}_{12}\text{N}_6\text{O}_{10}$ , DNDO, CAS RN [82744-29-4], is a symmetrical molecule and a nitramine with a higher molecular weight and lower vapor pressure than some of the other NENAs which are also used as plasticizers.

1,8-Dinitroxy-3,6-dinitrazaoctane

It has a molecular mass of 328.19 g/mol, a melting point (measured) of 333–335 K (60–62 °C), and a predicted density of  $1.593 \pm 0.06 \text{ g/cm}^3$  at 293 K (20 °C).

A more energetic derivative of GTN would be a GTN where one or more of the nitrate ester groups on the propane skeleton have been replaced by nitramino groups. 1-Nitramino-2,3-dinitroxypropane and 1,2,3-trinitraminopropane were prepared by multistep reactions from the corresponding amines and characterized by means of multinuclear NMR ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ), vibrational spectroscopy, elemental analysis, mass spectrometry, DSC, and TGA [156]. Heats of combustion were measured by oxygen bomb calorimetry and validated by quantum theoretical methods. Both compounds are superior in their performance data to GTN and PETN. In comparison to GTN the sensitivities towards mechanical stimuli was greatly reduced. 1-Nitramino-2,3-dinitroxypropane crystallized in the monoclinic space group *P*21 with an XRD density of  $1.799 \text{ g/cm}^3$ , while 1,2,3-trinitraminopropane crystallized in the orthorhombic space group *Pnma* with an XRD density of  $1.783 \text{ g/cm}^3$ . 1-Nitramino-2,3-dinitroxypropane

melts at 338 K (65°C) and started to decompose at 443 K (170°C). 1,2,3-Trinitraminopropane melts at 406 K (133°C), starts to decompose at 456 K (183°C) and has an enthalpy of formation of +1.450 kJ/g (for comparison: PETN -1.590 kJ/g, GTN -1.548 kJ/g).

## 6 Nitroalkylnitramines

Nitroalkylnitramines are useful plasticizers, similar to nitroalkylnitramines (nitroxyalkylnitramines).

The simplest nitroalkylnitramine would be nitromethylnitramine,  $\text{O}_2\text{NCH}_2\text{NHNO}_2$ , but this compound is not stable. One will typically want to have at least two carbon atoms between the nitro group and the nitramine group to obtain better stability. The next homologues would be 2-nitroethylnitramine  $\text{O}_2\text{NCH}_2\text{CH}_2\text{NHNO}_2$ , and its isomer, nitromethylmethylnitramine  $\text{O}_2\text{NCH}_2\text{N}(\text{NO}_2)\text{CH}_3$ , but they still lack the desired thermal stability.

The next step to more energetic nitroalkylnitramines are those that contain nitro groups on both alkyl groups flanking the nitramino group, such as bis(2-nitroethyl)nitramine  $\text{O}_2\text{N}-\text{CH}_2\text{CH}_2\text{N}(\text{NO}_2)\text{CH}_2\text{CH}_2\text{NO}_2$ , 1,5-dinitro-3-nitrazapentane. Each of the terminal carbon atoms in the  $\beta$ -position of the ethyl groups can carry not only one, but also two or even three nitro groups to make an even more energetic molecule.

Seven linear dinitramines including 5-methyl-2,4-dinitro-2,4-diazaheptane (MDNH), 2,6-dimethyl-3,5-dinitro-3,5-diazaheptane (DMDNH), 2,4-dinitro-2,4-diazaheptane (DNH), and 5,7-dinitro-5,7-diazaundecane (DNU) were synthesized by condensation reactions of nitramines with formaldehyde in an acidic medium, recrystallized for purification, and crystal structures, melting points, melting enthalpies, glass transition temperatures, and densities were measured [157]. Some of the results are summarized in Table 14. When plotting the melting points versus molecular mass, a sine-wave shaped curve developed, with melting points depending on the level of symmetry in the molecule.

### 6.1 *gem*-Dinitroethylnitramines

Most of the work described so far has dealt with nitramines that carried only one nitro group in the alkyl chain of carbon atoms with a  $\text{C}-\text{NO}_2$  group. The oxygen balance of such compounds can be improved by inserting two or more nitro groups into the alkyl side chain of carbon atoms. But will those dinitroalkylnitramines be thermally stable? The thermal decomposition of C,N-disubstituted *gem*-dinitroethylnitramines in dilute solutions in inert solvents is a first-order reaction and it is unaffected by the polarity of the solvent [158]. The rate constant is largely controlled by the steric effect of the substituent at the carbon atom bearing the *gem*-nitro groups. A correlation was found

**Table 14:** Thermal and density data of dinitramines.

| Compound abbreviation | Melting point |      | Melting enthalpy<br>J/g | Glass transition point |       | Density, pycn.<br>g/cm <sup>3</sup> |
|-----------------------|---------------|------|-------------------------|------------------------|-------|-------------------------------------|
|                       | K             | °C   |                         | K                      | °C    |                                     |
| DNDA5                 | 327.5         | 54.4 | 102.3                   | 228.7                  | −44.4 | 1.498                               |
| DNDA6                 | 304.7         | 31.6 | 108.2                   | 214.8                  | −58.3 | 1.419                               |
| DNDA7                 | 348           | 75   | 163.9                   | 263                    | −10.1 | 1.384                               |
| MDNH                  | 334.6         | 61.5 | 106.3                   | —                      | —     | 1.396                               |
| DMDNH                 | 358.2         | 85.1 | 127                     | —                      | —     | 1.323                               |
| DNH                   | 309           | 36   | 110                     | 215.5                  | −57.6 | —                                   |
| DNU                   | 345           | 72   | 125                     | —                      | —     | —                                   |

Data source: [157]

between the rate constant and the steric constant *E* of the substituent. This correlation permitted prediction not only of thermal stability of yet unexplored compounds, but also of an eventual change of the decomposition mechanism.

Bis(2,2-dinitroethyl)nitroamine can be synthesized by oxidative nitration of the condensation products from nitromethane and formaldehyde with sodium nitrite and silver nitrate, a subsequent reaction with KOH leading to potassium 2,2-dinitroethanol, followed with a Mannich condensation with ammonia, and finally nitration with fuming nitric acid and concentrated sulfuric acid [159].

Bis(2,2-dinitroethyl)nitramine-based salts (BDNENA salts) can be formed by replacing the trinitro group with a *gem*-dinitro group. A C-deprotonated anion could be obtained by deprotonation of BDNENA to form salts paired with nitrogen–hydrogen-rich cations. Energetic bis(2,2-dinitroethyl-*N*-nitro)ethylenediamine-based salts exhibiting favorable physical properties, good detonation properties, and relatively low impact sensitivities were synthesized in high yield by direct reactions of bis(2,2-dinitroethyl-*N*-nitro)ethylenediamine with organic bases such as aqueous ammonia, ethylenediamine, hydrazine hydrate, guanidine, aminoguanidine, diaminoguanidine, triaminoguanidine, 3,4,5-triamino-1,2,4-triazole, and *N*-carbamoylguanidine [160, 161]. The resulting salts were characterized by multinuclear <sup>1</sup>H and <sup>13</sup>C NMR, IR, DSC, and elemental analysis. Thermal decomposition kinetics and several thermodynamic parameters of some salts were obtained under nonisothermal conditions by DSC. The densities of the energetic salts paired with organic cations were in the range 1.60–2.02 g/cm<sup>3</sup> as measured with a gas pycnometer. Based on the measured densities and calculated heats of formation, predicted detonation pressures and velocities were calculated and found to be 23.6–44.8 GPa and 7790–9583 m/s, which makes them potentially useful as energetic materials. The most dense and thermally most stable salts was the guanidinium salt with a density of 2.02 g/cm<sup>3</sup>, an onset of decomposition at 414 K (141 °C) and an enthalpy of formation of +59.40 kJ/mol.

Addition reactions of polynitro alcohols with 2-nitro-2-azapropyl isocyanate yield symmetrically and asymmetrically substituted nitramino carbamate derivatives [61].

## 6.2 *gem*-Trinitroethylnitramines

Bis-(2,2,2-trinitroethyl)nitramine, di(2,2,2-trinitroethyl)nitramine,  $C_4H_4N_8O_{14}$ , BTNENA, is one of the few explosives with a positive oxygen balance: +14.4%.

BTNENA

It has a molecular weight of 389.1 g/mol and a nitrogen content of 28.80%. The enthalpy of formation data reported in the literature range from  $-27.6 \text{ kJ/mol} = -71.2 \text{ kJ/kg} = -17.0 \text{ kcal/kg}$  ([86, 133]) to  $+13 \text{ cal/g} = +5.06 \text{ kcal/mol} = +21.2 \text{ kJ/mol}$  [17].

Bis(2,2,2-trinitroethyl)nitramine (BTNENA) with a detonation velocity of 8661 m/s and a density of  $1.97 \text{ g/cm}^3$  was used as the main ingredient in some composite explosives in China, but this type of energetic material is no longer used because of its high sensitivity and chemical instability.

The theoretical enthalpies of gaseous bis(2,2,2-trinitroethyl)nitramine and derivatives in which one or several  $-\text{NO}_2$  groups were substituted by  $-\text{NF}_2$  and/or  $-\text{ONO}_2$  groups were calculated by a density functional theory method using different basis sets [162].

Depending on which method was used, the enthalpy of formation of the compound above was predicted to be between +104 and +159 kJ/mol, which does not match any of the measured values. One of the substituted compounds was 1,1,3,5,5-pentanitro-1,5-bis(difluoroamino)-3-azapentane

Depending on which method was used, the enthalpy of formation of the compound above was predicted to be between +35 and +74 kJ/mol. The heats of formation decreased with progressive  $-\text{NF}_2$  and  $-\text{ONO}_2$  substitution for  $-\text{NO}_2$ , but the heat of explosion increased as  $-\text{ONO}_2$  and  $-\text{NO}_2$  groups were replaced by  $-\text{NF}_2$  groups.

The similar energetic compound (2-fluoro-2,2-dinitroethyl)-2,2,2-trinitroethyl-nitramine

was synthesized and characterized by XRD, IR, Raman, NMR, elemental analysis, MS, and DSC [163]. The heats of formation were calculated by quantum mechanical methods. Predicted detonation pressure, detonation velocity, energy release, and adiabatic temperature were computed. The sensitivity towards impact, friction, and ESD was determined using the BAM standardized test methods.

### 6.3 Bis-2,2-dinitropropylnitramine

The thermal decomposition of *N*-nitro-*N*-bis-(2,2-dinitropropyl)amine, also known as *N,N*-bis(2,2-dinitropropyl)nitramide,  $C_6H_{10}N_6O_{10}$ , BDNPN

BDNPN

proceeds with autoacceleration [164]. The molecule is composed of two *gem*-dinitropropyl groups bonded to a central nitramine group. The first step of the process is monomolecular. The nature of the substituents in nitroamines did not influence the energy of dissociation of the  $N-NO_2$  bond. The increased reactivity of the compounds studied in comparison with *N*-nitrodialkylamines is due to the positive contribution to the entropy of activation, associated with steric hindrances to rotation around the  $N-NO_2$  bond.

Bis(2,2-dinitropropyl)-nitramine has a density of  $1.78 \text{ g/cm}^3$ . It crystallizes with two formula weights in the C-centered monoclinic space group  $C2$  (no. 5) with unit cell parameters  $a = 10.726(4) \text{ \AA}$ ,  $b = 5.992(3) \text{ \AA}$ ,  $c = 10.400(4) \text{ \AA}$ , and  $\beta = 110.01(3)^\circ$  [165]. A comparison of the thermochemical data of BDNPN, RDX, and TNAZ revealed that BDNPN has the highest impetus and lowest flame temperature within this group of molecules. See also [166].

If the 1,3,3-trinitro derivative of azacyclobutane, TNAZ, was an open-chain nitroalkylnitramine, it would be discussed here. However, because the nitro groups are attached to a closed ring, azetidine, the properties of TNAZ are discussed in the chapter "Heterocyclic Amines" in this set, based on the structure of the ring molecule to which the nitro groups have been attached.

## 7 Azidoalkylnitramines

Three nitramines containing 2-azido-1,1-dinitroethyl groups have been synthesized. One of these compounds, 1,7-diazido-2,2,4,6,6-pentanitro-4-azaheptane, possesses a high density of  $1.835 \text{ g/cm}^3$ , and some of the physical and safety properties are also reported [167].

Based on the modification of molecular structure of nitroform nitramines, one azidomethyl group was introduced into the molecule to replace one nitro group of nitroform nitramines, and three high energy density *gem*-dinitroazidoalkylnitramines were synthesized, identified, and characterized [168]. The *gem*-dinitroazidoalkylnitramines have high density ( $1.7\text{--}1.8 \text{ g/cm}^3$ ), high nitrogen content (ca. 40%), satisfactory oxygen balance ( $-23$  to  $-35\%$ ), high positive enthalpy of formation (ca.  $+500 \text{ kJ/mol}$ ), and acceptable thermal stability (thermal decomposition onset temperature ca.  $473 \text{ K} = 200^\circ\text{C}$ ).

A group of azidoalkylnitramines have been evaluated as plasticizers for gun propellants, including 1,6-diazido-2,5-dinitrazahexane (DADNH), 1,5-diazido-2,4-dinitrazapentane (DADZP), 1,3-diazido-2-nitrazapropane (DANP) 1,5-diazido-3-nitrazapentane (DANPE also known as DIANP), and 1,7-diazido-2,4,6-trinitrazaheptane (DATH) [169]. It is projected that impetus values  $>1400 \text{ J/g}$  will be possible at flame temperatures of approximately  $\sim 3500 \text{ K}$ . If flame temperature was not a constraint, impetus values above  $1500 \text{ J/g}$  would be possible.

Diazido nitramines offer significantly more impetus than RDX and have impetus values as neat ingredients ranging from  $1500$  to  $1750 \text{ J/g}$ . Unfortunately, these nitramines have very high isochoric flame temperatures  $T > 4000 \text{ K}$ , and hence, are of limited usefulness due to high barrel wear. New compounds are required which have the proper stoichiometry to generate lower molecular weight gases, and a suitable  $\Delta H_f$  to provide a reasonable flame temperatures [170].

When examining the kinetic laws and mechanisms of the thermal decomposition of azidonitramines in the gaseous phase, in molten state, and in solutions, it was found that homolysis is a first order reaction, and the rate limiting stage has Arrhenius's parameters  $E_a = 144.8\text{--}166.5 \text{ kJ/mol}$ ,  $\log A = 13.53\text{--}14.97$ , what is not typical for monofunctional alkylazides and alkylnitramines [171]. The thermolysis of the azido group initiates decomposition. Nitramino groups in  $\beta$ - or  $\alpha$ -position to azido groups increase the decomposition rate by 1–2 orders of magnitude, as compared with nitramino groups in the  $\delta$ -position.

### 7.1 1-Azido-2-nitro-2-azapropane and 1-Azido-3-nitro-3-azapentane

1-Azido-2-nitro-2-azapropane, also known as 1-azido-2-nitrazapropane, *N*-(azido-methyl)-*N*-methyl-nitramide, 1-azido-*N*-methyl-*N*-nitromethanamine,  $\text{C}_2\text{H}_5\text{N}_5\text{O}_2$ , ANAP, CAS RN [55680-29-0],  $M = 131.093$  g/mol,

1-Azido-2-nitro-2-azapropane

was synthesized from 1-chloro-2-nitro-2-azapropane and sodium azide [172]. The highly energetic compound was characterized using vibrational (IR and Raman) and multinuclear NMR spectroscopy ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ), elemental analysis, and low-temperature single crystal XRD. 1-Azido-2-nitro-2-azapropane represents a covalently bound liquid energetic material which contains both a nitramine unit and an azide group in the same molecule. It was hydrolytically stable at ambient conditions and was very sensitive to friction and impact stimuli. See also [173].

An even more energetic nitramine molecule can be synthesized when both methyl groups carry an azido group:

1,3-Diazo-2-nitrazapropane

This energetic compound is called 1,3-diazo-2-nitrazapropane or *N,N*-bis(azido-methyl)nitramide, DANP, 1-azido-*N*-(azidomethyl)-*N*-nitromethanamine,  $\text{C}_2\text{H}_4\text{N}_8\text{O}_2$ , CAS RN [67362-62-3], molecular mass 172.106 g/mol. 1,3-Diazo-2-nitrazapropane is a colorless liquid with an oxygen balance of  $-37.2\%$ , a nitrogen content of  $65\%$ , a melting point of  $265\text{ K } (-8^\circ\text{C})$ , a density of  $1.430\text{ g/cm}^3$ , and an enthalpy of formation of  $+583\text{ kJ/mol } (+139.3\text{ kcal/mol}, +809\text{ cal/g})$ . The reduced-pressure boiling point at  $0.45\text{ mm Hg}$  is  $370\text{ K}$  at  $60\text{ Pa}$  ( $97^\circ\text{C}$  at  $0.45\text{ mm Hg}$ ).

Another azidoalkyl nitramine is ethyl 2-azidoethylnitramine, 1-azido-3-nitro-3-azapentane, *N*-(2-azidoethyl)-*N*-ethyl-nitramide, 2-azido-*N*-ethyl-*N*-nitroethanamine or 2-azido-*N*-ethyl-*N*-nitroethylamine, ethylAENA,  $\text{C}_4\text{H}_9\text{N}_5\text{O}_2$ , CAS RN [89130-64-3],

molecular mass 159.15 g/mol, which carries only one terminal azido group on one of the two ethyl groups

Ethyl 2-azidoethylnitramine  
 $\text{H}_3\text{CCH}_2\text{N}(\text{NO}_2)\text{CH}_2\text{CH}_2\text{N}_3$

Ethyl 2-azidoethylnitramine is a colorless liquid with a melting point below 258 K ( $-15^\circ\text{C}$ ), a density of  $1.200\text{ g/cm}^3$ , and an enthalpy of formation of  $+205.6\text{ kJ/mol}$  ( $+48.9\text{ kcal/mol}$ ,  $+307\text{ cal/g}$ ).

A similar azidoalkylnitramine is *N*-(azidomethyl)-*N'*-methyl-*N,N'*-dinitro-methanediamine, 1-azido-2,4-dinitrazapentane,  $\text{C}_3\text{H}_7\text{N}_7\text{O}_4$ , CAS RN [1414934-28-3], but very little is known about it:

1-Azido-2,4-dinitrazapentane

One of its homologues is 1-azido-3,5-dinitro-3,5-diazahehexane, 1-azido-3,5-dinitrazahexane, also known as *N*-(2-azidoethyl)-*N'*-methyl-*N,N'*-dinitro-methanediamine,  $\text{C}_4\text{H}_9\text{N}_7\text{O}_4$ , CAS RN [201596-35-2] which has a melting point of  $307.6\text{--}398.6\text{ K}$  ( $34.5\text{--}35.5^\circ\text{C}$ )

1-Azido-3,5-dinitrazahexane

An energetic plasticizer containing nitramino, azido, and nitroxyl groups in a linear molecular structure, pentanol-3-nitrazo-5-azido nitrate, 2-[2-azidoethyl(nitro)-amino]ethyl nitrate, PNAN, was synthesized via reaction in dimethyl sulfoxide

solution, using 1,5-dinitrato-3-nitrazapentane (DINA) and sodium azide as starting materials [174]. The structure of PNAN was characterized by IR,  $^1\text{H}$  NMR, and elemental analyses. The density was  $1.46\text{ g/cm}^3$ , decomposition temperature  $445\text{ K}$  ( $172^\circ\text{C}$ ), glass transition temperature  $232\text{ K}$  ( $-41^\circ\text{C}$ ), viscosity  $19.5\text{ mPas}$ , friction sensitivity  $12\%$ , and impact sensitivity  $56\%$ .

Pentanol-3-nitrazapentane (PNAN)

## 7.2 1,5-Diazido-3-nitrazapentane

1,5-Diazido-3-nitrazapentane, also known as 1,5-diazido-3-nitro-3-azapentane, *N,N*-bis(2-azidoethyl)nitramide,  $\text{C}_4\text{H}_8\text{N}_8\text{O}_2$ , DIANP, DANPE, CAS RN [89130-65-4], carries one terminal azido group on each of the two ethyl groups of a nitramine

1,5-Diazido-3-nitrazapentane

The oxygen balance of DANPE is  $-79.93\%$  and the nitrogen content is  $55.98\% \text{ N}$ .

### 7.2.1 Preparation of DANPE

1,5-Diazido-3-nitrazapentane (DANPE) was synthesized from *N*-nitrodihydroxyethylamine dinitrate  $\text{O}_2\text{NO}-\text{CH}_2-\text{CH}_2-\text{N}(\text{NO}_2)-\text{CH}_2-\text{CH}_2-\text{ONO}_2$  (DINA) and sodium azide, via azidation, extraction, washing, filtration, and vacuum distillation [175]. Its structure was characterized by IR, NMR, and elemental analyses. A parametric study of the optimum reaction conditions for synthesizing DANPE (=DIANP) identified the following optimum operating conditions: mass ratio of DINA to sodium azide about  $1 : 0.59$ ; solvent DMSO; reaction temperature  $353\text{--}358\text{ K}$  ( $80\text{--}85^\circ\text{C}$ ), and reaction time  $7\text{--}8\text{ h}$ . The yield of DANPE (=DIANP) was about  $80\%$  and purity was  $98\%$ . In a similar effort, the optimum conditions for a  $73\%$  yield and  $99.6\%$  purity were as follows: reaction temperature  $373\text{ K} = 100^\circ\text{C}$ , reaction time  $6\text{ h}$ , standing for

3–5 days [176]. The organic impurity was separated and characterized as 1-hydroxy-5-azido-3-nitrazapentane.

1,5-Diazido-3-nitrazapentane can also be synthesized using diethylnitramine dinitrate and sodium azide as starting materials [177]. The kinetic equation describing this synthesis reaction was established and the effect of temperature on the reaction rate was studied. The results indicated that the reaction is of second order under these experimental conditions. The rate constants of the reaction at temperatures of 363, 366, 368, and 371 K (90, 93, 95, and 98 °C) were  $2.11 \times 10^3$ ,  $4.72 \times 10^3$ ,  $6.55 \times 10^3$ , and  $1.20 \times 10^2 \text{ dm}^3 \text{ mol}^{-1} \text{ min}^{-1}$ , respectively. The apparent activation energy  $E_a$  and pre-exponential factor  $A$  of this reaction were 28.87 kJ/mol and  $7.67 \times 10^3 \text{ L/min}$ .

1,5-Diazido-3-nitrazapentane has been made by reacting diethanolamine and nitric acid to form 1,5-dinitrato-3-nitrazapentane (DINA) and then reacting the DINA with metal azide to form the 1,5-diazido-3-nitrazapentane [178, 179].

A two-step process for producing 1,5-diazido-3-nitrazapentane (DANPE = DIANP) involves the steps of nitrating diethanolamine with nitric acid in a halogenated solvent such as methylene chloride to form 1,5-dinitrato-3-nitrazapentane (DINA) as an intermediate, solvent transferring DINA from the halogenated solvent to DMSO, adding sodium azide to the resulting solution to form DANPE as the product, and solvent-transferring DANPE from the DMSO to another halogenated solvent, e.g., methylene chloride [180–182]. Thus, both DINA intermediate and DANPE product can be prepared in solution, and both can also be purified in solution, eliminating the necessity for isolating the neat, hazardous compounds.

An improved preparation of 3-nitro-1,5-diazido-3-azapentane was described and some properties of four azido compounds were determined [183]. The heat of combustion of 1,5-diazido-3-nitrazapentane is 3265.3 kJ/mol (16.313 kJ/g). The standard enthalpy of formation of 1,5-diazido-3-nitrazapentane is +539.74 kJ/mol (+2696.5 J/g).

### 7.2.2 Properties of DANPE

DANPE is a yellow liquid with a melting point of 276 K (2.7 °C = 37 °F) and a boiling point (with incipient decomposition) of 500 K (227 °C = 441 °F). The density of DANPE is  $1.330 \text{ g/cm}^3$ . The enthalpy of formation of DANPE is +594 kJ/mol (+141.9 kcal/mol = +709 cal/g). Other sources [112] gave a heat of combustion of 3899 cal/g and an enthalpy of formation of +540 kJ/mol (+129.0 kcal/mol). In the DSC, the first signs of exotherms are observed at 519 K = 246 °C. 1,5-Diazido-3-nitrazapentane lowers the flame temperature in gun and rocket propellants without visual lessening of burning rates. In addition, the azido nitramine produces low molecular weight combustion products. Applications of DANPE as a plasticizer in solid propellants are discussed in Section 7.2.9. See also [184].

In order to be active as a plasticizer, 1,5-diazido-3-nitrazapentane, DANPE, has to be soluble in nitrocellulose and miscible with other plasticizers. The solubility parameters of DANPE were estimated by a group contribution method and determined

experimentally by turbidity titration [185]. The solubility of DANPE in different solvents was studied and the results showed that the estimated values were in accordance with the determined ones. The solubility parameter of DANPE was determined as  $22.29 \text{ (J/mL)}^{1/2}$ .

### 7.2.3 Mixtures Containing DANPE

Pure 1,5-dinitrato-3-nitrazapentane (DINA) and 1,5-diazido-3-nitrazapentane (DANPE) are solids at room temperature, but a eutectic mixture of the two is a liquid at room temperature and has a freezing point below  $\sim 248 \text{ K}$  ( $\sim -25^\circ\text{C}$ ) [186, 187]

### 7.2.4 Analysis of DANPE

Trace impurities in purity standard 1,5-diazido-3-nitroazapentane DANPE can be analyzed by GC [188]. The sample was dissolved by THF, and separated by a capillary column ( $30 \text{ m} \times 0.32 \text{ mm}$ ,  $5 \mu\text{m}$ ) with temperature programming. The external standard method was employed for quantitative analysis. The relative standard deviations of determination results were 2.16–2.67% ( $n = 6$ ).

The assay of 1,5-diazido-3-nitrazapentane can also be determined by potentiometric titration in DMSO as solvent, first adding sodium hydroxide solution to hydrolyze the azide, then adding an excess of  $\text{AgNO}_3$  to precipitate the azide as  $\text{AgN}_3$  and back titrating with 1-N bromide solution [189]. The purity of standard DANPE was 99.85% and the relative standard derivation was 0.13%. There was no significant variation between the results obtained by electrochemical titration and HPLC.

### 7.2.5 Thermal Decomposition of DANPE

A numerical method of computing the kinetic parameters (the activation energy  $E_a$ , the pre-exponential constant  $A$  and the reaction order  $n$ ) of exothermic decomposition of energetic materials via an exothermic rate equation was applied to six energetic materials [190]. The values of  $E_a$ ,  $A$ , and  $n$  were measured for the exothermic decomposition of six typical energetic materials including 1,6-diazido-2,5-dinitrazahexane (I), 1,5-diazido-3-nitrazapentane (II), 2,2,4,7,9-hexanitro-5-methyl-4,7-dinitrazadecane (III), 2,2,2-trinitroethyl-4,4,4-trinitrobutyrate (IV), 1,4-dinitro-2,3-dioxo-1,4-dinitrazacyclohexane (V), and others.

The thermal decomposition behavior of several energetic plasticizers including DANPE (1,5-diazido-3-nitrazapentane) was investigated in 10 mass-% solutions in toluene by adiabatic self heating in an accelerating rate calorimeter (ARC) and the effect of solvent and sample cell was eliminated by extrapolation [111]. At the lowest detectable heat flow of  $25 \mu\text{W/g}$ , DANPE had a relatively low extrapolated onset of thermal decomposition temperature of  $379.2 \text{ K}$  ( $106.1^\circ\text{C}$ ), while GAP was predicted to start to decompose at about  $387 \text{ K}$  ( $114^\circ\text{C}$ ). The activation energy of the decomposition of DANPE was  $167.3 \pm 0.2 \text{ kJ/mol}$  and the pre-exponential factor was  $9.903 \times 10^{14} \text{ s}^{-1}$ .

### 7.2.6 Molecular Structure of DANPE

A set of linear aliphatic azido nitramines was designed on paper (on screen) and studied by density functional theory methods to find new promising azido nitramines applicable to propellants as plasticizers and to investigate the effect of the methylene nitramino group  $(-\text{CH}_2\text{NNO}_2-)_n$  on performance [191]. The reliability of the predictions of the theoretical method was tested by comparing the theoretical densities with experimental data. The thermodynamic properties (heat capacity, enthalpy and entropy of formation), density  $\rho$ , detonation pressure  $P$ , detonation velocity  $D$ , specific impulse  $I_{\text{sp}}$ , and stability were predicted. With an increase in the number  $n$  of  $(-\text{CH}_2\text{NNO}_2-)_n$  groups, the thermodynamic properties,  $\rho$ ,  $P$ , and  $D$  increased, while the stability decreased slightly. There were linear relationships between thermodynamic properties and  $n$ . Each  $-\text{CH}_2\text{NNO}_2-$  group improved the enthalpy of formation by 67.59 kJ/mol on average. It reached a maximum when  $n = 4$  and changed little when  $n \geq 5$ . Similar  $(-\text{CH}_2\text{NNO}_2-)_n$  studies were performed for cyclic nitramines instead of linear nitramines. It is worth noting that the  $I_{\text{sp}}$  values of all linear compounds were higher than that of HMX.

### 7.2.7 Safety Properties of DANPE

The sensitivity safety properties of 1,5-diazo-3-nitrazapentane and its responses to heat or mechanical stimuli were measured under different levels of severity of the stimuli [192]. At the same time, TNT equivalence of DANPE was tested at different shock wave overpressures to identify the hazard level of DANPE manufacturing plants. The experimental results showed that DANPE cannot be ignited by igniters or flames, and the self-initiation temperature of DANPE was 499 K (226 °C). The TNT equivalence of DANPE in the shock wave overpressure range of 0.02 to 0.3 MPa was 0.4–0.6.

### 7.2.8 Toxicity of DANPE

DANPE is fairly toxic by dermal absorption and by ingestion. The compound has no potential for causing sensitization. The DANPE exhibited increases in chromosomal aberrations and a positive mutagenic response in cell cultures [193, 194]. It was recommended to use extreme caution to prevent DANPE from coming into contact with the skin since studies indicate this material is an effective skin penetrant. In the event of skin contamination, one must flush immediately with large volumes of water. Abrasive soap may increase absorption through the skin. Protective clothing should be worn by workers when there is the potential for accidental contact and splash guards should prevent splashing onto people or onto equipment that people handle. Work clothing should be changed if it becomes contaminated with DANPE.

A 90-day application of DANPE has the potential to cause testicular hypospermatogenesis in male rabbits and an apparent inhibition of mature ovarian follicles formation in female rabbits [195]. A no-observed-adverse-effect level was not achieved in the male rabbits but was achieved in female rabbits at the 27.3 mg/kg dose level.

A 2- and 6-week feeding of DANPE caused testicular hypospermatogenesis in male rats and pneumonitis in female rats [196]. A no-observed-adverse-effect level (NOAEL) was not achieved in male rats but was achieved in female rats at the  $56 \text{ mg kg}^{-1} \text{ day}^{-1}$  level. An oral approximate lethal dose (ALD) value for DANPE in male rats was  $1498 \text{ mg/kg}$  and in female rats it was  $617 \text{ mg/kg}$ . DANPE had a dermal toxicity ALD of  $2129 \text{ mg/kg}$  for male rabbits and  $3192 \text{ mg/kg}$  for female rabbits. DANPE has a primary eye irritant classification of “c” producing mild injury to the cornea. In addition, some injury to the conjunctiva was found. It has a skin irritant classification of “I” producing no primary irritation of the intact skin or no greater than mild primary irritation of the skin surrounding an abrasion. DANPE produced no sensitization reaction in guinea pigs.

### 7.2.9 Applications of DANPE

In view of the proposed application of DANPE as an energetic plasticizer for single-base and double-base propellants, the interaction of DANPE with NC has been studied by experiments and by computational models.

The processing characteristics, microstructures, and mechanical properties of an azidoalkylnitramine-plasticized gun propellant and a double-base gun propellant which were both prepared by a method avoiding volatile solvents were studied by means of a two roller calender, scanning electron microscopy (SEM), and a tensile strength tester [197]. The results indicated that the rolling and plasticizing temperature, plasticizing times, and molding pressure of the azidoalkylnitramine-plasticized gun propellant for the high nitrogen contents (12.6% N or 13.0% N) of NC were lower than those of a conventional NC/GTN double-base gun propellant. DANPE can efficiently plasticize the high nitrogen content of NC. The mechanical properties of the gun propellant with DANPE were improved within a wide range of temperatures. The plasticizing action of DANPE on the high nitrogen content of NC was better than that of GTN.

The mechanical properties, binding energies, and radial distribution functions of pure substances (NC, GTN, DIANP) and NC/DIANP and NC/GTN blends were calculated by molecular dynamics simulations [198]. Results showed that DANPE weakens the rigidity of NC networks and improves its plasticity. This action of DANPE on NC is better than that of GTN. The mechanical properties (modulus) of NC/DANPE blends are related to binding energies. A greater binding energy corresponds to higher mechanical modulus, which is thought to be due to a stronger interactive force between NC and GTN compared to that of NC with DANPE.

The plasticizing effect of DANPE on NC, four NC with different nitration degrees (7.2, 9.5, 10.4, and 12.0% N) as well as binary DANPE/NC mixtures with mass ratios of 1:3 were designed in a computer and investigated by molecular dynamic simulations with the COMPASS force field [199]. For comparison, GTN and GTN/NC mixtures with the mass ratio of 1:3 were also simulated. The miscibility of the mixtures was predicted using solubility parameters. The solubility parameters obtained from the MD

simulations were in reasonable agreement with few experimental data. The mechanical properties, e.g., elastic coefficients, modulus, Cauchy pressure, Poisson's ratio, were predicted and the results showed that both GTN and DANPE can effectively improve the mechanical properties of NC. Mechanical properties are better at higher temperatures. For the NC with higher N%, DANPE has better plasticizing effects than the conventional plasticizer GTN, while the situation is reversed for the NC with lower N%.

Similar molecular dynamics and dissipative particle dynamics simulations were performed to investigate the compatibility and mechanical properties of DANPE with GAP for different simulated chain length ( $n$ ) of GAP with  $n = 5, 10, 20, 30$ , and  $40$  [200]. Results showed that GAP and DANPE have good miscibility with each other. Compared with the mechanical properties of the pure GAP, it was found that addition of DANPE can enhance the plastic properties of GAP for improved tenacity and ductility.

A series of computations of substituted diazidoalkylene compounds based on  $N_3(CH_2)_nN_3$  for  $n = 5, 7, 9$ , such as azidoalkylnitramines, azidoalkyl nitrates, and azidoalkyl nitro compounds, predicted that azidoalkylnitramines would possess the best energetic properties, similar to azidoalkyl nitrates which were predicted to have the best thermodynamic properties [201]. These substituents slightly decreased the thermal stability and the azido nitrate esters had the worst thermal stability. Systematical inspection of the substituent effect can direct experimental researchers to synthesize modified azido compounds purposefully and selectively. Results showed that  $-NNO_2$ ,  $-NO_2$ , and  $-ONO_2$  all can improve the thermodynamic and energetic properties and the performance increases with the increasing number of substituent groups. The improvement contribution to the thermodynamic properties in decreasing order was  $-ONO_2 > -NO_2 > -NNO_2$ , and that to the energetic properties was  $-NNO_2 > -ONO_2 > -NO_2$ .

### 7.3 1,3-Diazido-2-nitrazapropane

1,3-Diazido-2-nitrazapropane, also known as 1,3-diazido-2-nitro-2-azapropane, 1-azido-*N*-(azidomethyl)-*N*-nitromethanamine,  $N_3CH_2N(NO_2)CH_2N_3$ ,  $C_2H_4N_8O_2$ , DANP, is a sufficiently stable compound and one of the most powerful liquid explosives with a high enthalpy of formation and a low freezing point.

1,3-Dihydroxy-2-nitrazapropane is a by-product of RDX production by nitration of urotropine (hexamethylenetetramine). Due to the extreme susceptibility of this compound towards hydrolysis, it can be transformed into a more stable diacetate ester through the reaction with sodium acetate in acetic acid. Azidation then leads to DANP. Other synthetic routes to 1,3-dihydroxy-2-nitrazapropane are described in the literature starting from nitramide, nitrourethane, or urea.

DANP can be made by reacting 1,3-dichloro-2-nitrazapropane with an aqueous solution of sodium azide, extracting the solution with methylene chloride, and separat-

ing the 1,3-diazido-2-nitrazapropane from the extracted solution by distillation [202]. The 1,3-dichloro-2-nitrazapropane was made from 1,3-diacetoxy-2-nitrazapropane.

An alternative method to prepare 1,3-diazido-2-nitrazapropane (DANP) involves the following five stages: (1) nitration of urea to make *N,N'*-dinitrourea [203], (2) condensation of the nitration product with formaldehyde to make 1,3-dihydroxy-2-nitrazapropane, (3) acylation (chlorination) of 1,3-dihydroxy-2-nitrazapropane, (4) chlorination of 1,3-diacetoxy-2-nitrazapropane with HCl, and (5) azidation of the dichloro derivative to make DANP [204]. This synthesis method is selective and enables isolation of pure 1,3-diazido-2-nitrazapropane free from impurities. Physical properties of DANP are summarized in Table 15.

**Table 15:** Physical properties of DANP.

| Property                  | SI units                 | Other units   |
|---------------------------|--------------------------|---------------|
| Molecular mass            | 172.11 g/mol             | 5.8102 mol/kg |
| Melting point             | 265 K                    | −8 °C         |
| Freezing point            | 216 K                    | −57 °C        |
| Density                   | 1.4320 g/cm <sup>3</sup> | —             |
| Decomposition temperature | > 423 K                  | > 150 °C      |
| Refractive index at 23 °C | 1.5265                   | —             |
| Enthalpy of formation     | +4330 kJ/kg              | +745 kJ/mol   |
| Detonation velocity       | 7108 m/s                 | —             |

Data source: [204]

A detailed theoretical investigation of 1,5-diazido-3-nitrazapentane (DANP) and 1,7-diazido-2,4,6-trinitrazaheptane (DATNH) was carried out using density functional theory and molecular mechanics computational methods [205]. The crystal structures, spectra, thermodynamic properties, heats of formation, detonation velocity, detonation pressure, specific impulse, and thermal stability were estimated. Possible initiation steps of pyrolysis were the breaking of N—NO<sub>2</sub>, C—N<sub>3</sub>, and N—N<sub>2</sub> bonds for both compounds and the cyclization of the adjacent nitro and azido groups for DATNH. Results showed that the rupture of N—NO<sub>2</sub> and N—N<sub>2</sub> (via hydrogen transfer) may happen simultaneously as the initial step of pyrolysis. DANP has higher stability than DATNH, while DATNH has better detonation performance than DANP. DANP has a lower specific impulse than RDX, while DATNH has a higher specific impulse than RDX.

#### 7.4 1,5-Diazido-2,4-dinitrazapentane and 1,6-Diazido-2,5-dinitrazaheptane

1,5-Diazido-2,4-dinitrazapentane, also known as *N,N'*-bis(azidomethyl)-*N,N'*-dinitromethanedi-amine, *N*-(azidomethyl)-*N*-[[azidomethyl(nitro)amino]methyl]nitramide, C<sub>3</sub>H<sub>6</sub>N<sub>10</sub>O<sub>4</sub>, CAS RN 55680-28-9, DADZP, with an oxygen balance of −32.5%, is

a colorless solid with a melting point of 353 K ( $80^{\circ}\text{C} = 176^{\circ}\text{F}$ ) and a density of  $1.700\text{ g/cm}^3$ .

1,5-Diazido-2,4-dinitrazapentane

The enthalpy of formation of DADZP is  $+751\text{ kJ/mol}$  ( $+179.6\text{ kcal/mol} = +730\text{ cal/g}$ ).

The only difference between the previous compound and the following symmetrical dinitramine compound is the additional methylene group in the center of the molecule. 1,6-Diazido-2,5-dinitrazahexane, *N,N'*-bis(azidomethyl)-*N,N'*-dinitro-1,2-ethanediamine, also known as *N*-(azidomethyl)-*N*-[2-[azidomethyl(nitro)-amino]ethyl]nitramide

1,6-Diazido-2,5-dinitrazahexane

CAS RN [40627-93-8], DADNH, EDANN,  $\text{C}_4\text{H}_8\text{N}_{10}\text{O}_4$ , is a colorless solid with a molecular mass of  $260.18\text{ g/mol}$ , a melting point of  $349\text{ K}$  ( $76^{\circ}\text{C}$ ), a density of  $1.610\text{ g/cm}^3$ , and an enthalpy of formation of  $+590\text{ kJ/mol}$  ( $+141.0\text{ kcal/mol} = +542\text{ cal/g}$ ). The onset temperature of exothermic decomposition as determined by an ATK Thiokol simulated bulk autoignition test was  $386\text{ K}$  ( $113^{\circ}\text{C} = 235^{\circ}\text{F}$ ). Another azidonitramine in this category is *n*-butyl azidoethylnitramine (BuAENA).

### 7.5 *n*-Butyl Azidoethylnitramine

The heat of reaction of the synthesis process of *n*-butyl azidoethylnitramine, also known as *N*-(2-azidoethyl)-*N*-*n*-butyl-nitramide, BuAENA,

*n*-Butyl azidoethylnitramine

was measured using a calorimeter [206]. The apparent kinetic parameters of the process were obtained by Levenberg-Marquardt's algorithm for least-squares estimation of nonlinear parameters. The results showed that in the process, the enthalpy of reaction ( $\Delta H$ ) was  $-18.1 \text{ kJ/mol}$ . The adiabatic temperature rise  $\Delta T$  was  $11.1 \text{ K}$ , the reaction order was  $0.97$  for BuNENA and  $0.05$  for  $\text{NaN}_3$ , respectively. The activation energy of the reaction was  $15.31 \text{ kJ/mol}$ , and the pre-exponential constant was  $0.27 \text{ mol} \cdot \text{m}^{-3} \cdot \text{s}^{-1}$ .

*n*-Butyl(2-azidoethyl)nitramine has a refractive index of  $n_D^{24} = 1.4870$ , a freezing point below  $195 \text{ K}$  ( $-78^\circ\text{C}$ ), and a very low impact sensitivity beyond the range of the instrument ( $>150 \text{ in. lb}$ ) [207].

## 8 Cyanoalkylnitramines

Cyanoalkylnitramines (nitiloalkylnitramines) carry a cyano group in the alkyl rest which would increase their heat of combustion. Examples are 2-cyanoethylnitramine, *N*-nitro-2-cyanoethylamine, *N*-(2-cyanoethyl)nitramide, 3-(nitroamino)propanenitrile,  $\text{C}_3\text{H}_5\text{N}_3\text{O}_2$ , CAS RN [62984-38-7],  $M = 115.091 \text{ g/mol}$ :

2-Cyanoethylnitramine

The hydrogen on the NH group is quite acidic and forms metal salts. Thermal decomposition kinetics of sodium, potassium, rubidium, and copper salts of *N*-nitro-2-cyanoethylamine were studied in melt by a manometric method combined with IR spectroscopy [208]. The rate constant was practically independent of the metal cation nature. The limiting stage in the decomposition reaction may be the homolysis of the C–N bond to form cyanoethyl and metal nitramide radicals, based on parameters of the Arrhenius equation and activation entropy for the limiting stage.

## 9 Linear Trinitramines

Every NH group adjacent to an  $\text{NO}_2$  group is acidic and a variety of salts have been formed from nitramines, including nitramines that contain more than one  $-\text{NH}-\text{NO}_2$  group.

### 9.1 2,4,6-Trinitro-2,4,6-triazaheptane

The simplest trinitramine is 2,4,6-trinitro-2,4,6-triazaheptane, also known as *N,N*-bis-[[methyl(nitro)amino]methyl]nitramide, *N*-methyl-*N'*-[[methyl(nitro)amino]methyl]-

*N,N'*-dinitromethanediamine, TNAHP,  $C_4H_{10}N_6O_6$ , CAS RN [13126-25-5],  $M = 238.159$  g/mol,

TNAHP

with a melting point of 440–442 K and a heat of fusion of 34.0 kJ/mol.

## 9.2 1,7-Diazido-2,4,6-trinitro-2,4,6-triazaheptane

Trinitramines with terminal azido groups have lower vapor pressure than many other compounds with comparable energy content. One example is 1,7-diazido-2,4,6-trinitrazaheptane, also known as *N,N*-bis[[azidomethyl(nitro)amino]methyl]nitramide, *N*-(azidomethyl)-*N'*-[[[(azidomethyl)(nitro)amino]methyl]-*N,N'*-dinitromethanediamine, DATH,  $C_4H_8N_{12}O_6$ , CAS RN [62209-57-8],  $M = 320.183$  g/mol:

1,7-Diazido-2,4,6-trinitrazaheptane

which is a solid with a molecular mass of 320.19 g/mol, an oxygen balance of –30%, a melting point of 277 K (4 °C), and an enthalpy of formation of +613 kJ/mol (+146.5 kcal/mol = +458 cal/g). Other sources listed a melting point of 379 K (136 °C).

1,7-Diazido-2,4,6-trinitro-2,4,6-triazaheptane (DATH) was synthesized in 75.3% yield starting with urotropine as precursor by nitration, chlorination, and azido substitution steps [209]. The density of DATH was 1.71 g/cm<sup>3</sup>, melting point 408–410 K (135–137 °C), detonation velocity 8300 m/s ( $\rho = 1.64$  g/cm<sup>3</sup>), heat of combustion 10800 kJ/kg, temperature of onset of decomposition 465 K (192 °C), friction sensitivity 25 kg<sub>f</sub>/cm<sup>2</sup>, impact sensitivity 25 cm with a 2-kg weight.

Adding azide-containing ingredients such as 1,7-diazido-2,4,6-trinitrazaheptane (DATH) and/or 1,6-diazido-2,5-dinitrazaheptane (DADNH) as oxidizers and 1,3-diazido-2-nitrazapropane (DANP) as a plasticizer results in improved solid propellants [210]. It was found that compatible propellants with acceptable physical properties could be formulated from these ingredients. Furthermore, the high energy potential of these systems was verified by ballistic testing.

The thermal decomposition characteristics of 1,7-diazido-2,4,6-trinitrazaheptane (DATH) and multicomponent systems containing DATH were studied by using DSC, TGA, and differential thermogravimetric analysis (DTG) techniques [211]. Based on mass loss measurements, three  $\text{—NO}_2$  groups in the DATH molecule break away first from the main chain when DATH is heated up to 473 K (200 °C). Following this process, the azido groups and the residual molecule decomposed rapidly to release a great amount of heat within a short time. In the multicomponent systems, DATH underwent a strong interaction with the binder of the double-base propellant and a weak interaction with RDX. The burning rates of two typical NC-based propellants were determined by using a Crawford bomb. The results showed that the burning rate rose by about 19–66% when 23.5% DATH was substituted for RDX in a minimum smoke propellant.

The thermal decomposition behavior of a low-signature propellant containing 1,7-diazido-2,4,6-trinitrazaheptane (DATH) was investigated by DSC, TGA, and differential thermogravimetric analysis (DTG) [212]. Several analysis methods were used to study the physicochemical structure of surface before and after combustion and the burning flame structure of this kind of propellant. Because DATH decomposes to produce a great quantity of  $\text{N}_2$  gas, the structure of burning surface of the propellant is obviously different from that of RDX-CMDB propellants. The evolution of  $\text{N}_2$  gives rise to the formation of many bubbles and pores on the burning surface. These pores can increase the burning rate because of extending the burning surface and increasing thermal-transfer intensity. In comparison with decomposition and combustion processes of RDX-CMDB propellants, the propellant containing DATH creates different decomposition products from the condensed phase to the fizz zone.

### 9.3 1,2,3-Trinitraminopropane

1,5-Dinitro-3-nitramino-1,5-diazapentane, 1,2,3-trinitraminopropane, 1,2,3-tris-nitraminopropane, *N*-(2,3-dinitramidopropyl)nitramide, TRINP,  $\text{C}_3\text{H}_7\text{N}_6\text{O}_6$ ,  $\text{O}_2\text{NNHCH}_2\text{CH}(\text{NHNO}_2)\text{CH}_2\text{NHNO}_2$ , can be made from glycerol via a six-step synthetic method [213, 214]. Glycerol was converted to the 1,2,3-triaminopropane and nitrated to form 1,2,3-trinitraminopropane with an onset of thermal decomposition at 456 K (183 °C). Trinitraminopropane is an analog to trinitoxypropene, glycerol trinitrate, where all nitrate groups have been replaced by nitramino groups.

1,2,3-Trinitraminopropane melts at 406 K (133 °C), has an XRD density of 1.753 g/cm<sup>3</sup>, and has a predicted enthalpy of formation of +1450 kJ/kg (for comparison: PETN: −1590 kJ/kg). The calculated detonation pressures were 35.62 GPa (for comparison: PETN: 31.39 GPa). The calculated detonation velocities were 8933 m/s (for comparison: PETN: 8564 m/s). Other properties of TRINP are listed in Table 16 along with those of PETNA. Table 17 contains a list of properties of TRINP and its ammonium, hydrazinium, and hydroxylammonium salts.

## 10 Linear and Branched Tetranitramines

### 10.1 Pentaerythritol-Based Nitramines

Pentaerythritol is well known as a backbone for pentaerythritol tetranitrate (PETN), a powerful explosive and next to RDX and HMX one of the most widely used explosives.

Replacing the nitrate ester groups in PETN with nitramine groups results in an even more powerful explosive, pentaerythritol tetranitramine, *N*-[3-nitramido-

Table 16: Properties of pentaerythritol tetranitramine and 1,2,3-trinitraminopropane.

| Compound name                           | Gross formula     | Molecular mass | Onset of thermal decomposition |            | Density <sup>a</sup> | Enthalpy of formation |        | Predicted detonation pressure | Predicted detonation velocity | Impact sensitivity |

Data source: [215]

2,2-bis(nitramidomethyl)propyl]nitramide, PETNA, that exists as colorless crystals at ambient temperature, melts at 439.9–440.5 K (166.8–167.4 °C) (with incipient decomposition) and thermally decomposes at 456 K (183 °C). A similar compound can be formed starting with 1,2,3-propanetriol [213, 214]. The properties of pentaerythritol tetranitramine and 1,2,3-trinitraminopropane are summarized in Table 16 in comparison to those of PETN and RDX.

Polynitramines, pentaerythritol tetranitramine (PETNA) and 1,2,3-trinitraminopropane (TRINP), were treated with aqueous ammonia, hydrazine hydrate, or hydroxylamine in methanol at room temperature to obtain their corresponding salts in excellent isolated yields [215]. All new compounds were characterized by IR, NMR, DSC, and elemental analysis. Their energetic properties, such as impact sensitivity, detonation velocity, and detonation pressure, were also determined and compared with existing energetic compounds, such as PETN, RDX, and TNT. The properties of these compounds are listed in Table 17.

Impact sensitivities of all the compounds and salts were measured by using a BAM fall hammer apparatus with a 10 kg drop-weight and found to be no lower than 15 J. All the salts were less sensitive than the molecular precursors PETNA or TRINP as well as PETN (2.9 J) or RDX (7.4 J). The densities of salts were found to be slightly less than those of the parent acids.

## 10.2 Linear Azidoalkyltetranitramines

### 1,9-Diazido-2,4,6,8-tetranitro-2,4,6,8-tetrazanonane

1,9-Diazido-2,4,6,8-tetranitro-2,4,6,8-tetrazanonane

can be made by reacting 1,9-dichloro-2,4,6,8-tetranitro-2,4,6,8-tetrazanonane or 1,9-dinitroxy-2,4,6,8-tetranitro-2,4,6,8-tetrazanonane with sodium azide in dimethylformamide [216].

## 11 Open-chain Heterocyclic Nitramines

The name “heterocyclic nitramines” can apply to heterocyclic compounds like RDX where the nitramino group is part of the ring structure, or it can apply to heterocyclic compounds which carry a nitramino group as a ligand outside the ring structure. Both types are suitable as high energy density materials (HEDMs).

Trying to find the correct location to place the information on RDX in the book at hand depended on making a decision whether to list it here under nitramines (subsequent to open-chain linear nitramines) or list it in a chapter under heterocyclic compounds with triazines. This would mean that HMX also had to be moved as well to the

end of the chapter on 6- (and 8-) membered ring heterocyclic compounds. The decision was made to list RDX and HMX not under heterocyclic compounds but here in the same chapter as linear nitramines. Up to this point, the chapter was reserved for open-chain and linear nitramines. Now we start looking at nitramines that contain rings. This section contains information on  $RN(NO_2)R$  compounds where one or both R groups are heterocyclic rings. Examples of such nitramines are listed on pages 6 and 7 of a patent [217]. Example 5 of that patent describes a 1,1'-(2-nitrazo-1,3-propanediyl)-3,5-dinitro-1,2,4-triazole, which is truly a very energetic compound, a white crystalline powder, which melts at 468 K (195 °C) and explodes at 473 K (200 °C).

## 12 Six-Membered Ring Heterocyclic Nitramines

### 12.1 Six-Membered Ring Heterocyclic Nitramines with Two Nitrogens in the Ring

1,3,5,5-Tetranitrohexahydropyrimidine, DNNC,  $C_4H_6N_6O_8$ , CAS RN [81360-42-1],  $M = 266.126$  g/mol, has been considered as a replacement for RDX and even as a replacement for AP in solid propellants. The total oxygen content is 48.1% and the oxygen balance is -18%, which is better than that of RDX (-21.6%).

1,3,5,5-Tetranitrohexahydropyrimidine

DNNC was synthesized in small samples in a three-step procedure with 25-g batches, and the density was  $\rho = 1.82$  g/cm<sup>3</sup>, the enthalpy of formation was  $\Delta H_f = +46$  kJ/mol = +11 kcal/mol, and the melting point was 424–427 K (151–154 °C) [218]. The onset of exotherm in the DSC was 492 K (219 °C).

### 12.2 Six-Membered Ring Heterocyclic Nitramines with Three Nitrogens in the Ring

Cyclo-1,3,5-trimethylene-2,4,6-trinitramine, RDX, is unique in terms of thermal stability and energy content. In the search for even better cyclic nitramines, the effects of the structure of cyclic *N*-nitramines on the rate and mechanism of their thermolysis

were examined [219]. Manometry together with IR spectroscopy, mass spectrometry, and vapor gas chromatography were used to study the thermolysis of six-membered cyclic *N*-nitramines containing one, two, or three nitramine building blocks, as well as attached oxo, *gem*-dinitro, azide, nitroimino, amino, and tetrazolyl functional groups. This showed an effect of the conformation and functional groups on the rate, mechanism, and activation parameters of the rate limiting stage of thermolysis.

### 12.2.1 1,3,5-Trinitro-1,3,5-triazacyclohexane, Hexogen, Cyclonite, RDX

Cyclo-1,3,5-trimethylene-2,4,6-trinitramine, also known as 1,3,5-trinitro-1,3,5-triazacyclohexane, cyclotrimethylenetrinitramine, trimethylenetrinitramine, hexahydro-1,3,5-trinitro-1,3,5-triazine, 1,3,5-trinitroperhydro-1,3,5-triazine, 1,3,5-trinitrohexahydro-*s*-triazine, 1,3,5-trinitro-1,3,5-triazinane, hexogen, cyclonite, RDX,  $C_3H_6N_6O_6$ , CAS-RN [121-82-4],  $M = 222.12 \text{ g/mol}$ , oxygen balance  $-21.6\%$ , is a widely used energetic additive for solid propellants and an important explosive. Preparation and properties of RDX and HMX and similar heterocyclic nitramines are summarized here in the chapter “Nitramines” compounds instead of the chapter “Heterocyclic Amines,” which deals with all other heterocyclic ring compounds. Cyclic nitramines, which are heterocyclic compounds, are presented here. Applications of RDX in solid rocket propellant formulations (nitramine propellants) will be discussed in future sets on solid propellants. There is so much published information on RDX that a complete compilation would cover an entire book in its own right. This section, embedded in the chapter on heterocyclic nitramine compounds, is only an incomplete survey of some of the information on RDX that might be of interest to rocket propellant formulators. The references cited here are only a random collection of references from the vast literature, an incomplete list, but they give our readers a useful starting point for further research. Most of the publications cited in this section were motivated by the use of RDX and HMX as explosives and not their use as rocket propellant ingredients. Nevertheless, the propellant users benefit from the vast amount of information that was initially intended for the use of RDX and HMX as explosives. Next to AP and NC, RDX may be one of the most frequently used solid ingredients for solid rocket propellants. We do not discuss its application as an explosive here because that would fill another book, which can also be said for HMX. Most books on rocket propellants and explosives contain fairly detailed sections with information on RDX, so the reader who does not find the needed information in the section at hand will have no difficulty finding the necessary information in other sources.

#### 12.2.1.1 History of RDX

Cyclotrimethylenetrinitramine (RDX) was first patented in 1899 by Henning for medicinal use [220]. Its value as an explosive was not recognized until 1920 by Herz. Herz succeeded in preparing RDX by direct nitration of hexamine, but the yields

were low and the process was expensive and unattractive for large-scale production. After publication of von Herz's patents in 1920 [221, 222], the Armament Research Department at Woolwich, UK, began its investigation of RDX (British code name for **R**esearch **D**epartment **E**xplosive or **R**oyal **D**emolition **E**xplosive became the commonly used name for this compound). As a result of this research, the batch process was changed to a continuous flow process. RDX was not used as such as the main filling in British shells and bombs during World War II, but was added to TNT to increase the power of the explosive compositions. During the World War II, hexogen was manufactured in large quantities on both sides, using several different methods.

The oxygen balance of RDX is  $-21.6\%$  and it is thus substantially underoxidized. It is not correct to rank RDX as an oxidizer among the nitramine propellant ingredients.

#### 12.2.1.2 Preparation, Production, and Availability of RDX

The "classical" method of RDX production (Henning 1898) was the direct nitration of hexamethylene tetramine to hexogen using concentrated nitric acid. The concentrated reaction mixture was poured into iced water, and the product precipitated out. Hexamethylene tetramine has six methylene groups but RDX needs only three; thus, three methylene groups must be destroyed or split off by oxidation.

Most RDX is produced in crystalline form by one of two different manufacturing processes. The Woolwich or "nitric acid" process used by Société Nationale des Poudres et des Explosifs (SNPE) in France produces almost pure RDX with few impurities. The Bachmann [223] or "aceto-nitric" process produces mixed products of approximately 79% RDX, 6% HMX, and 15% intermediates. RDX produced by the Bachmann process may contain 4–17% HMX as a contaminant. This process is also called "KA process" (inventors: Knöffler and Apel; in USA: "Bachmann process"), where hexamethylenetetramine dinitrate is reacted with ammonium nitrate and a small amount of nitric acid in an acetic anhydride medium, forming hexamethylenetetramine dinitrate as an intermediate. By using hexamine dinitrate in lieu of formaldehyde only half the amount of water was produced, thus, requiring one half the usual amount of acetic anhydride. The waste acetic acid thus formed can be concentrated, subjected to the so-called ketene process, recycled, and the regenerated acetic anhydride can be re-used.

A continuous nitration of hexamethylenetetramine ("S-H process" after the inventors Schnurr and Henning) using highly concentrated nitric acid, accompanied by a decomposition reaction under liberation of nitrous gases, without destruction of the hexogen formed is patented [224]. The reaction mixture is then filtered to separate the product from the waste acid, followed by stabilization of the product by boiling under pressure and, if required, recrystallization.

In the K process (after the inventor Knöffler), an increased yield can be obtained by the addition of ammonium nitrate to the nitration mixture of hexamethylene tetramine and nitric acid, followed by warming. The formaldehyde that is split off as a by-product formed more hexamethylenetetramine with the added ammonium nitrate and was converted by the nitric acid into hexogen.

There are hundreds of publications dealing with the nitration (nitrolysis) of hexamethylene tetramine leading to a multitude of products; for instance, some papers have been published as a series of papers [225–231].

Another series of publications reported studies on the nitrolysis of hexamethylenetetramine by NMR spectrometry which is a good method to monitor the progress of the reaction and identify some of the intermediates *in situ* as they form and then are quickly consumed in the transformation into other products [232]. In another process, paraformaldehyde and ammonium nitrate are reacted in an acetic anhydride medium with formation of hexogen.

There is considerable variation between RDX batches from the various manufacturers as measured by card gap, critical diameter, and fragment impact tests. The explanation for these differences appears to lie in the crystal morphology rather than in any differences in chemical composition, but a major problem is that accurate information on the manufacturing processes and subsequent treatment of the commercial samples is usually not known.

Intermediates of the RDX/HMX synthesis process are not intended to be used as explosives by themselves, but they are useful tools in explaining the synthesis reactions and optimizing the yield and selectivity of the process. Instead of interrupting the synthesis and capturing the intermediates such as 1-acetylhexahydro-3,5-dinitro-1,3,5-triazine (TAX) and 1-acetyloctahydro-3,5,7-trinitro-1,3,5,7-tetrazocine (SEX) before they are consumed and end up as RDX or HMX, there are other methods to prepare the intermediates and use them to study the multistep synthesis process of RDX and HMX [233].

### 12.2.1.3 Crystallization of RDX

RDX that is to be incorporated in composite-modified double-base propellants must have a carefully controlled particle size and particle shape. The desired particle shapes can be obtained by crystallizing RDX from different solvents. At the same time, recrystallization removes impurities [234]. The effect of different solvents on the crystallization of RDX has been thoroughly investigated. Very useful information on the crystallization of chemicals with special reference to RDX and HMX has already been published [235], including nicely illustrated information on the best crystallization methods for RDX and HMX using different solvents and cooling rates.

Nano-RDX can be prepared by evaporation assisted solvent–antisolvent interaction [236]. Nanoparticles of RDX can be prepared by a simple re-precipitation method using acetone as solvent and water as the antisolvent. The effects of changing experimental parameters such as ratio of solvent to antisolvent, temperature of antisolvent during injection, and concentration of solution on particle size and morphology of RDX were systematically studied. The size of the particles was characterized using dynamic light scattering and field emission scanning electron microscopy. The mean particle size of the RDX nanoparticles according to SEM analysis ranged from 40 to 230 nm under different conditions of preparation. The UV/Vis absorption max-

imum of nano-RDX was found to be blue-shifted when compared to the absorption maximum for bulk RDX. Powder XRD results showed that RDX nanoparticles precipitated in a stable  $\alpha$ -RDX crystalline polymorph form. Fourier transform infrared (FTIR) spectroscopy was used to characterize the chemical nature of the nano-RDX. Thermal characterization of the RDX-nanoparticles was performed using simultaneous thermogravimetric analysis coupled with differential scanning calorimetry (TGA-DSC).

A significant research and development effort was made and is still ongoing on crystallization processes in order to master crystal quality, particle shapes, and/or size distributions of RDX and RDX replacements such as NTO. In the case of RDX or I-RDX, the objective is to reach the highest limit of shock insensitiveness thanks to a process developed and patented by the French–German Institute of Saint Louis (ISL) [237]. With the help of ISL scientists, EURENCO was able to produce at pilot scale several batches of VI-RDX (VI stands for very insensitive), which were proven to equal shock sensitivities of VI-RDX produced by ISL at laboratory scale and is now producing IRDX<sup>®</sup>. Chemring Nobel is also producing crystalline RDX [132].

### 12.2.2 Physical Properties of RDX

The physical properties of RDX are summarized in Table 18. Additional data for a wider range of temperatures are provided in the subsequent sections of this chapter.

**Table 18:** Physical properties of hexogen (RDX).

| Property                                 | SI units                |               | Other units    |           | References |
|------------------------------------------|-------------------------|---------------|----------------|-----------|------------|
| Molecular mass                           | 222.1163 g/mol          | 4.5021 mol/kg | —              | —         | [85]       |
| Melting point                            | 477 K                   | —             | 204 °C         | 399 °F    | [133]      |
| Density at 293 K                         | 1.82 g/cm <sup>3</sup>  | —             | —              | —         | [133]      |

Data source: [133]

Additional information on properties of RDX is available in the well-known common information sources [239–243].

RDX and four other high explosives were analyzed thoroughly in a round robin analysis exercise, comparing the results obtained in several international (NATO) laboratories on identical samples [244]. Although this report also contains information on the thermal stability, sensitivity, and physical properties of five high explosives (RDX, HMX, TNT, PETN, and tetryl), it is referenced mostly here in the RDX section because of the five explosives described, RDX is the only one that is actually used in substantial quantities in nitramine propellants. The report contains very clean IR and NMR spectra of the five explosives.

### 12.2.2.1 Melting Point of RDX

The melting point of RDX is  $477\text{ K} = 204\text{ °C} = 399\text{ °F}$ . In a DTA, RDX containing 0.2% HMX started to melt at  $465\text{ K}$  ( $192\text{ °C}$ ) and the maximum melting endotherm was at  $473\text{ K}$  ( $200\text{ °C}$ ). The same report [244] lists the melting point of RDX as  $474.9\text{--}475.5\text{ K}$  ( $201.9\text{--}202.5\text{ °C}$ ). NIST Chemistry WebBook [85] referenced a paper by Hall [245], which gave m.p. =  $478.5\text{ K} = 205.4\text{ °C}$ . The RDX used by Krien, Licht, and Zierath [87] melted at  $475.8\text{ K}$  ( $202.7\text{ °C}$ ).

The melting and thermodynamic properties of RDX were examined using a diamond anvil cell apparatus capable of pressures exceeding 10 kbar (1000 MPa) and  $523\text{ K}$  ( $250\text{ °C}$ ) [246]. The slope of the melting temperature versus applied pressure curve for RDX, as determined in a diamond cell, was found to be  $4.09 \pm 0.6\text{ °C/kbar}$  ( $0.0409 \pm 0.006\text{ °C/MPa}$ ). The density of liquid RDX at its melting point was calculated from this slope to be approximately  $1.63\text{ g/cm}^3$ . A phase diagram of binary RDX/HMX mixtures is shown in Figure 23 in Section 15.2.1.

### 12.2.2.2 Vapor Pressure of RDX

Knowledge of the vapor pressure of explosives like RDX is important for the ability to detect explosives in clandestine illegal operations. The vapor pressure of strand-burning RDX determines how much RDX evaporates before it decomposes in the flame front. RDX in nitramine propellants would sublime and leave vacant hollow spaces if it was too volatile when the propellant is exposed to high temperatures in tropical climates. The difficulty with measuring vapor pressure of RDX at higher temperatures beyond its melting point is that the samples begins to decompose and gas evolution disturbs the pressure measurements.

The vapor pressure of RDX and several other high melting explosives was computed using the Langmuir equation which utilized the mass loss measurements taken in a heated vacuum apparatus [247, 248]. The following equation was applicable to the temperature range of  $329\text{--}371\text{ K}$ :

$$\log_{10} P = 14.18 - 31110/(4.576 \times T)$$

where  $P$  is the pressure in mm Hg and  $T$  is the temperature in kelvin. The vapor pressure of RDX at  $321\text{ K}$  ( $48\text{ °C}$ ) is  $10^{-7}\text{ mm Hg}$ .

The vapor pressure of RDX was measured using a DSC method that placed RDX in a sealed cell of known volume with a small hole of known diameter at the top [249]. The data were curve-fitted and gave the vapor pressure equation

$$\log_{10} P = 7.678 - 4415.908/T$$

where  $P$  is the pressure in atm and  $T$  is the temperature in kelvin.

The vapor pressure of RDX was measured through isotope dilution analysis and a nonfragmenting field ionization mass spectrometer, and it was noted that their data were not consistent with those obtained by effusion methods and varied significantly

at some temperatures [250]. Data collected at temperatures of 347.15, 357.15, and 369.15 K was fitted to the Clausius–Clapeyron equation:

$$\log P = \frac{\Delta H}{2.303RT_0} - \frac{\Delta H}{2.303RT}$$

where  $P$  is the vapor pressure in mm Hg,  $T$  is the temperature in kelvin,  $T_0 = 840$  K,  $\Delta H = 13.6$  kcal/mol, and  $R$  is the gas constant  $R = 0.00198588$  kcal mol<sup>-1</sup> K<sup>-1</sup>. In comparison, the data by John et al. [250] follows a different slope when the  $\log P$  vs.  $T^{-1}$  is graphed and compared. The RDX concentration in air at 298 K (25 °C) is 0.8 ppb v/v.

Dionne et al. measured the vapor pressure of RDX directly in the range of 298–413 K using a vapor pressure generator coupled with a cold trap using a military-grade RDX sample obtained from the Federal Bureau of Investigation (FBI) and no further purification or purity analysis was carried out [251]. The measured data were combined with literature data and for temperature range 309–411 K fitted to an equation of the type:

$$\log_{10} P = +22.50 - \left( \frac{6473}{T} \right)$$

where  $P$  is the pressure in ppt and  $T$  is the temperature in kelvin.

In addition to vapor pressures measured by static and dynamic methods, vapor pressures of self-burning energetic materials can be derived from the surface temperature of burning solid specimens [252]. The vapor pressure of RDX was measured by a comparative GC method [253]. For two homologous compounds, the  $\log P$  versus the retention time exhibits a linear relationship. Increasing the temperature in a GC column will decrease the retention time of the analyte. The data from the Reinig GC measurements [253] were curve-fitted to give the parameters for an Antoine vapor pressure equation

$$\log_{10} P = A - B/(C + T)$$

where  $P$  is the vapor pressure in mm Hg,  $T$  is the temperature in kelvin and  $A = 31.995$ ,  $B = 24883.728$ , and  $C = 313.210$  [253]. Figure 6 is a comparison of vapor pressure from the Antoine equation (solid line) with data from different authors

A critical review by Oestmark et al. looked at data from five papers that had been published on the vapor pressure of RDX and other explosives, trying to resolve discrepancies and establishing a baseline for comparison [254]. The combined data from four of those papers is illustrated in Figure 7, although three data sources are the same as the ones used for Figure 6. The figure also shows a Clausius–Clapeyron fit to this data, except the data from John [250] was excluded due to inconsistencies between values in the text and in the figure in his paper. It is possible to extrapolate the data in Figure 7 to room temperature using the Clausius–Clapeyron equation, but in order to obtain more reliable room temperature data, more exact measurements or possibly

**Figure 6:** Vapor pressure of RDX. (Reproduced and modified from [253], with permission from Dr. Michael Reinig 7 March 2021.)

**Figure 7:** Vapor pressure of RDX. (Republished and modified from [254], with permission from ©2012 John Wiley & Sons – Journals; permission conveyed through Copyright Clearance Center, Inc.)

modeling would be advisable. The Clausius–Clapeyron fit of the data for RDX led to the equation

$$\log P = A - \frac{B}{T} = 13.79 - \left( \frac{6637}{T} \right)$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin for the temperature range 310–411 K (37–138 °C). The vapor pressure for RDX at 298 K was extrapolated to be  $3.30 \times 10^{-9}$  mm Hg. The heat of sublimation is 127.1 kJ/mol (30.38 kcal/mol).

Additional vapor pressure data for RDX (and PETN and HMX) are available in the older literature [255, 256]. Thermodynamic data on evaporation and sublimation of RDX are listed in Table 19.

**Table 19:** Thermodynamic data on evaporation and sublimation of RDX.

| State of matter | Temperature interval (K) | Temperature dependence of pressure above condensed phase (pressure in atm) | Heat of evaporation (or sublimation) (kJ/mol) | References |
|-----------------|--------------------------|----------------------------------------------------------------------------|-----------------------------------------------|------------|
| Solid           | 343–447                  | $\ln P = 28.216 - 16143.4/T$                                               | (134.3)                                       | [256]      |
| Liquid          | 590–795                  | $\ln P = 19.925 - 12179.2/T$                                               | 101.3                                         | [252]      |

### 12.2.2.3 Density of RDX

The density distributions of six samples of Class 1 RDX were measured using the density gradient technique [238]. This technique was used in an attempt to distinguish between RDX crystallized by a French manufacturer (designated insensitive or IRDX) from RDX manufactured at Holston Army Ammunition Plant (HAAP), the current source of RDX for Department of Defense (DoD). Two samples from different lots of French IRDX had an average density of  $1.7958 \pm 0.0008$  g/cm<sup>3</sup>. The theoretical density of a perfect RDX crystal is 1.806 g/cm<sup>3</sup>. This yields 99.43% of the theoretical maximum density (TMD). For two HAAP RDX lots, the average density was  $1.786 \pm 0.002$  g/cm<sup>3</sup>, only 98.89% TMD. High performance liquid chromatography showed quantities of HMX in HAAP RDX. French IRDX also showed a 1.1 °C higher melting point compared to HAAP RDX in the DSC, consistent with no melting point depression due to the HMX contaminant. A second part of the program involved characterization of Holston RDX recrystallized using the French process. After reprocessing the average density of the Holston RDX was increased to 1.7907 g/cm<sup>3</sup>. The French IRDX contained no HMX, which is assumed to account for its higher density and narrower density distribution. Reprocessing of RDX from Holston improved the average density compared to the original Holston RDX, but the resulting HIRDX was not as dense as the original French IRDX. When the HRDX was reprocessed by SNPE to convert it to IRDX, the density distribution increased and the mean density increased to 1.791 g/cm<sup>3</sup> (99.04% TMD). Clearly, the French process for preparing IRDX was only partially successful in transforming the RDX from HAAP into IRDX of the same density as the original SNPE IRDX. Recrystallized Holston IRDX crystals were much larger (3–500 μm or more) than either the original Class 1 HAAP RDX or French IRDX.

The Peng–Robinson equation of state was applied to RDX, TNT, and RDX/TNT mixtures [257]. The pure RDX and TNT in both their liquid and solid phases, as well

liquid and solid mixtures of the two compounds were modeled for temperatures and pressures as high as 500 K and 2500 bar. The Peng–Robinson equation of state provided a good representation of experimental volumetric (e.g., density and bulk modulus), thermal (heat capacity), and phase behavior (melting temperature and solubility) data.

RDX crystals were grown during high acceleration (high g) in an ultracentrifuge [258]. These crystals were found to have a density  $\sim 0.6\%$  greater than crystals obtained at 1g and to have a greatly reduced defect content. The high-g crystals should therefore have significantly reduced shock sensitivity compared to commercial grade RDX. Crystal defects including voids and solution inclusions caused by temperature variation or evaporation at 1g are minimized and the RDX crystal density increases. A nitrogen pycnometer was used to measure the density of the RDX crystals grown at 1g and at 200000g. The density of the RDX crystals grown at 200000 g ( $1.7980 \pm 0.0003 \text{ g/cm}^3$ ) was found to be greater than the density of RDX crystals grown at 1g ( $1.7881 \pm 0.0003 \text{ g/cm}^3$ ) by  $0.0099 \text{ g/cm}^3$ . The density of the high-g crystal was 99.6% of the theoretical maximum density of RDX.

#### 12.2.2.4 Phase Transitions of RDX

RDX exists in several polymorphic modifications. The two simplest polymorphic forms of RDX are designated  $\alpha$ - and  $\beta$ -RDX. The structure of  $\alpha$ -RDX has been determined by single crystal neutron diffraction [259]. The structure of  $\beta$ -RDX has not been determined because of the difficulty of obtaining and preserving well-formed crystals, even for short periods, owing to its extreme instability under ambient conditions. Many of the physical properties and the sensitivity to stimuli leading to explosion depend on the modification the crystals are currently in. The transition temperatures and pressures of phase transitions in RDX are listed in Table 20.

**Table 20:** Transition temperatures and pressures of polymorphic phase transitions in RDX.

| Phase transition            | Temperature |        | Pressure |       |
|-----------------------------|-------------|--------|----------|-------|
|                             | K           | °C     |          |       |
| $\alpha \rightarrow \gamma$ | 295–460     | 22–187 | 3.7 GPa  |       |
| $\alpha \rightarrow \beta$  | 477         | 204    | 101 kPa  | 1 atm |

Raman spectroscopy and optical imaging were used to determine the phase boundaries between various RDX polymorphs on single crystals at pressures up to 8.0 GPa and temperatures ranging from room temperature to 550 K [260]. Several distinct pressure regions were found in the RDX response at elevated temperatures: (1) melting of  $\alpha$ -RDX followed by decomposition, below 2.0 GPa, (2) decomposition of  $\alpha$ -RDX between 2.0 and 2.8 GPa, (3) irreversible transformation of  $\alpha$ - and  $\gamma$ -RDX to  $\epsilon$ -RDX between 2.8 and 6.0 GPa, and (4) decomposition of  $\gamma$ -RDX above 6.0 GPa. A triple point between

the  $\alpha$ -,  $\gamma$ -, and  $\epsilon$ -RDX was found at 3.7 GPa and 466 K. The  $\alpha \rightarrow \gamma$  phase transition was confirmed to occur at the same pressure,  $\sim 3.7$  GPa, regardless of temperature, in the range of 295–460 K. Furthermore, it was determined that  $\epsilon$ -RDX (1) has limited chemical stability under the pressure and temperature conditions where it is produced and (2) decomposes according to the autocatalytic rate law. The high pressure-high temperature polymorph was inferred to be the not very well defined  $\beta$ -RDX phase in these studies (Figure 8).

**Figure 8:** RDX phase diagram. (Reprinted and adapted from [260], with permission from ©2010 American Chemical Society; permission conveyed through RightsLink.) Legend: Dark black lines are from (Baer, Oxley, and Nicol [261]) (dashed lines, extrapolation of experimental data). Red lines are from (Nicol, Oxley, and Baer [262]) (dashed line, approximate phase boundary between  $\gamma$ - and HP-HT-polymorphs).

Raman spectroscopy has been used to determine the phase diagram and phase behavior of RDX at pressures up to 16 GPa and at temperatures from 150 to over 450 K [261]. Two new stable solid polymorphs have been identified: a high pressure/low temperature form that converts reversibly to  $\alpha$ -RDX (the form stable at ambient conditions) at 3.8 GPa, independent of temperature from 150 to 375 K. There were indications of a high pressure/high temperature form of RDX that was highly metastable, showed a very large hysteresis, and probably was identical with the polymorph known as  $\beta$ -RDX.

In order to study the effect of isotope substitution on phase changes, the phase diagrams of RDX-h6 and RDX-d6 have been examined by Raman spectroscopy up to pressures of more than 13 GPa at 295 K and 7.5 GPa between 150 and 450 K [262]. Two stable high pressure phases have been found:  $\gamma$ -RDX or RDX-III formed from  $\alpha$ -RDX above 3.8 GPa below 380 K.  $\beta$ -RDX formed when  $\alpha$ - or  $\gamma$ -RDX were heated.  $\beta$ -RDX can be retained metastably at low temperatures and may be related to a very unstable form occasionally recovered at ambient pressure. Deuterium isotopic substitution increased the temperature where  $\beta$ -RDX began to form on heating.

Phase changes between three solid ( $\alpha$ ,  $\gamma$ ,  $\epsilon$ ), one liquid, and decomposed phases of RDX were examined in experiments on single crystals at pressures up to 12.0 GPa and temperatures to 600 K in a diamond anvil cell [263]. Several distinct pressure regions were found in the RDX response at elevated temperatures. The boundaries between the  $\alpha$ ,  $\gamma$ , and  $\epsilon$  phases were determined with a triple point at 3.7 GPa and  $\sim 466$  K. The  $\alpha \rightarrow \gamma$

phase transition was confirmed to be reversible and to occur at the same pressure 3.7 GPa, regardless of temperature. The  $\epsilon$ -phase was found to exist only in a narrow range of pressures, from 2.8 to 6.0 GPa. Below and above these pressures,  $\alpha$ - or  $\gamma$ -RDX crystals decomposed or melted instead of transforming to  $\epsilon$ -RDX. Both the  $\alpha \rightarrow \epsilon$  and  $\gamma \rightarrow \epsilon$  transitions were irreversible at the phase boundaries.

Three distinct solid phases were observed when high pressure and temperature structural changes for RDX were investigated at pressures up to 7.0 GPa and temperatures around 570 K in a diamond anvil cell apparatus using FTIR absorption, optical microscopy, and EDAX techniques [264]. The effects of pressure on the thermal decomposition kinetics as a function of RDX pressure were investigated using an IR absorption technique. Solid phase I ( $\alpha$ -RDX) was found to have a pressure enhanced reaction rate with an energy and volume of activation of 213 kJ/mol (51 kcal/mol) and  $-5.6 \text{ cm}^3/\text{mol}$ , respectively. Solid II was not observed to react and the observed reaction rate of solid III decreased with increasing pressure.

The  $\alpha$  and  $\beta$  phases of RDX were found to thermally decompose, while the  $\gamma$  phase transformed to either  $\alpha$  or  $\beta$  before reaching decomposition temperatures [265]. The decomposition rate of  $\alpha$  phase was found to increase with increasing pressure, suggesting a bimolecular-type mechanism.

A diamond anvil cell was used in conjunction with optical polarizing light microscopy (OPLM), FTIR, energy dispersive X-ray diffraction (EDAX), and micro FT-Raman spectroscopy to determine pressure/temperature/reaction phase diagrams for several nitramine compounds, including RDX and HNIW [266].

High-pressure phase transitions of RDX and HMX were studied in a diamond anvil cell with XRD and Raman spectroscopy [267]. The existence of a high-pressure phase, termed  $\delta$ -RDX, had not been confirmed until 2008, although it was suggested already nearly 20 years earlier. Very limited characterization of  $\delta$ -RDX existed and one of the primary goals of later studies was to investigate the temperature/pressure stability of this phase. The phase diagram of RDX was studied as a function of temperature and pressure by Raman spectroscopy at pressures up to 29 GPa and temperatures ranging from 4 to 298 K [268]. Three stable phases ( $\alpha$ ,  $\gamma$ , and  $\delta$ ) have been found and their phase stabilities have been investigated. Phase boundaries were studied as a function of pressure and temperature, permitting a delineation of the various polymorph stability fields. A pressure–temperature phase diagram is shown in Figure 9. The Raman spectra observed for the  $\delta$ -RDX phase as a function of temperature showed a larger number of vibrational modes in the Raman spectra than was noted in both the  $\alpha$ -RDX and  $\gamma$ -RDX spectra. This is probably due to an increase in the molecular symmetry as is found with  $\beta$ -RDX. New vibrational features near 235 and 430  $\text{cm}^{-1}$  were comparable to those previously reported for the  $\beta$ -RDX phase.

The linear coefficient of thermal expansion of RDX at 293 K is  $6.36 \times 10^{-5} \text{ K}^{-1}$  and the cubical coefficient of thermal expansion at 293 to 373 K is  $2.5 \times 10^{-4} \text{ K}^{-1}$ .

#### 12.2.2.5 Compressibility and Velocity of Sound of RDX

The compressibility of RDX crystals is anisotropic and depends on the crystal plane to which the load is applied. It also depends on the polymorph modification the crystal is currently in. The modification undergoes changes as pressure is applied. The compressibility of RDX has been studied both experimentally and theoretically–computationally. Compressibility is closely related to the speed of sound and the speed of sound is closely related to the detonation velocity of explosives like RDX. There are fewer experimental studies than computational studies.

#### Experimental Studies of RDX Compressibility

The propagation of detonation fronts and shock waves through RDX and other explosives depends on the compressibility of the material. The real-time, molecular-level response of oriented single crystals of RDX to shock compression was examined using Raman spectroscopy [269]. Single crystals of [111], [210], or [100] orientation were shocked under stepwise loading to peak stresses from 3.0 to 5.5 GPa. Two types of measurements were performed: (1) high-resolution Raman spectroscopy to probe the material at peak stress and (2) time-resolved Raman spectroscopy to monitor the evolution of molecular changes as the shock wave reverberated through the material. The frequency shift of the C–H stretching modes under shock loading appeared to be similar for all three crystal orientations below 3.5 GPa. Significant spectral changes were

observed in crystals shocked above 4.5 GPa. These changes were similar to those observed in static pressure measurements, indicating the rapid occurrence of the  $\alpha \rightarrow \gamma$  phase transition in shocked RDX crystals. The phase transition had an incubation time of  $\sim 100$  ns when RDX was shocked to 5.5 GPa peak stress. The  $\alpha \rightarrow \gamma$  phase transition under shock wave loading is connected to the onset of chemical decomposition in shocked RDX.

### Computational Studies of RDX Compressibility

Density functional theory and many other quantum chemical molecular modeling computational methods have been used by hundreds of investigators to predict the response of RDX and similar nitramines to sudden compression in a shock wave. Only a random sample of some of these studies is included here. Equations of state have been derived from measured compressibilities, from other measured molecular structure parameters, and from strictly theoretical considerations. The structural, electronic, and absorption properties of crystalline RDX under hydrostatic pressure of 0–50 GPa were studied using density functional theory [270]. As the pressure increased, the lattice constants and the unit cell volume gradually decreased. The compressibility of RDX crystal is anisotropic. The different changing trends of bond lengths and bond angles under pressures showed that both the ring opening and the N–NO<sub>2</sub> cleavage are possible to trigger the RDX decomposition. The interactions between electrons, especially for the valence electrons, are strengthened under the influence of pressure. The absorption spectra of RDX display more and stronger bands in the fundamental absorption region at high pressure.

Equations of state for the  $\alpha$  and  $\gamma$  polymorphs of RDX have been derived from their Helmholtz free energies [271]. The ion motion contribution to the Helmholtz free energy was represented by Debye models with density-dependent Debye temperatures that were parameterized to vibrational densities of states computed from dispersion-corrected density functional theory. By separating the vibrational density of states into low frequency modes of mainly lattice phonon character and high frequency modes of intramolecular character, it was possible to significantly improve the description of the heat capacity at low temperatures and the thermal contribution to the pressure. The static lattice energies for both polymorphs were constructed to reproduce published isothermal compression data. The equations of state have been applied to the prediction of the path of the principal Hugoniot in the equilibrium phase diagram.

#### 12.2.2.6 Solubility of RDX

RDX is practically insoluble in water. Its solubility in other solvents such as supercritical carbon dioxide is similar to that of HMX [272]. It is important to know the solubility of RDX if it has to be removed and possibly recycled from munitions during demilitarization with a suitable solvent. Solubilities of RDX in different solvents are listed in Table 21.

**Table 21:** Solubility of RDX in different solvents.

| Solvent                      | Solubility, g/100 mL solution at 303 K (30 °C), except <sup>a</sup> |
|------------------------------|---------------------------------------------------------------------|
| <i>N</i> -Methyl pyrrolidone | 73.7 <sup>a</sup>                                                   |
| Dimethyl sulfoxide           | 46 <sup>a</sup> (at 298 K = 25 °C)                                  |
| Dimethylformamide            | 34 <sup>a</sup>                                                     |
| $\gamma$ -Butyrolactone      | 16 <sup>a</sup>                                                     |
| Cyclopentanone               | 8.5 (at 298 K = 25 °C)                                              |
| Acetonitrile                 | 7.0                                                                 |
| Acetone                      | 6.9                                                                 |
| Nitromethane                 | 5.0                                                                 |
| Acetic anhydride             | 4.8                                                                 |
| Nitroethane                  | 3.0                                                                 |
| 1-Nitropropane               | 2.0                                                                 |
| 2-Nitropropane               | 2.0                                                                 |
| Propyl acetate               | 1.8                                                                 |
| Ethyl acetate                | 1.6                                                                 |
| Dioxane                      | 0.9                                                                 |
| Butyl acetate                | 0.8                                                                 |

<sup>a</sup> Grams/100 mL solvent

Data source: [273]

The objective of a program at Penn State University was to synthesize nano-sized energetic ingredients by rapid expansion of supercritical solution (RESS) process for future development of Insensitive Munitions (IM) systems using RDX as the model substance [274]. RDX was dissolved in supercritical CO<sub>2</sub> at 35.5 MPa (~5150 psig) and 329 K (56 °C) and sprayed through a 152  $\mu$ m (0.006 in.) nozzle into a low-pressure chamber. The solubility of RDX in supercritical CO<sub>2</sub> was very poor, so that higher pressure and temperature conditions and use of a co-solvent were considered to improve the output.

A technique of rapid expansion of supercritical solutions to produce nanocrystalline energetic materials was developed and characterized to produce nano-scale crystals of RDX. Nanocrystals of RDX were formed by expansion of supercritical solutions of RDX in carbon dioxide through a 100  $\mu$ m sapphire nozzle at initial pressures of 150–295 bar and temperatures of 323–363 K [275, 276]. Produced particles were characterized by field emission SEM, XRD, HPLC, and melting point analysis. The process produced particles with a mean size in the range of 110–300 nm with a narrow size distribution. The product was crystalline, as determined by XRD. This material would burn faster than macrocrystalline RDX.

The solubility of RDX in carbon dioxide was measured over a temperature and pressure range of 303 to 353 K and 6.9 to 48.3 MPa, respectively, and RDX was found to be relatively insoluble in CO<sub>2</sub>, with a maximum solubility of about 0.25 mg RDX/g CO<sub>2</sub> at the highest temperatures and pressures studied [272, 277–279].

### 12.2.2.7 Thermal Conductivity of RDX

Considerable discrepancies exist in the literature for values of the thermal conductivity of RDX. Thermal diffusivities and thermal conductivities of RDX and HMX were measured from room temperature into the decomposition region using a laser flash method [280, 281]. Thermal conductivities were calculated from the thermal diffusivity, specific heat, and density of each material.

The heat capacity, thermal conductivity, and thermal diffusivity of a range of other oxidizers, binders, and rocket propellants were determined and compared to literature data [282]. The thermal diffusivity  $\alpha$  of RDX for the range from 293 to 423 K (20 to 150 °C) can be described by the linear equation

$$\alpha = 1.52 \times 10^{-3} - 3.70 \times 10^{-6} t$$

where  $\alpha$  is the thermal diffusivity in  $\text{cm}^2/\text{s}$  and  $t$  is the temperature in °C. The thermal conductivity  $\lambda$  of RDX in the range from 293 to 423 K (20 to 150 °C) does not vary much with temperature and is close to

$$\lambda = 6.6 \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ } ^\circ\text{C}^{-1}$$

See also [283, 284].

### 12.2.2.8 Thermodynamic Properties and Thermal Properties of RDX

#### Heat Capacity of RDX

The specific heats of RDX and HMX were measured from room temperature into the decomposition region using a laser flash method [280, 281]. The specific heats of RDX and HMX are shown in Figure 10.

**Figure 10:** Heat capacities of RDX, HMX, and AP. (Reprinted and modified [280], with permission from ©1985 Old City Publishing granted by Dr. Ian Mellanby 10-May-2021)

The molar heat capacity of RDX in the range from 200–475 K (–73 to +202 °C) can be described by the following linear equation

$$C_p = 15 + 0.15 T$$

where  $C_p$  is the molar heat capacity in  $\text{cal mol}^{-1} \text{ } ^\circ\text{C}^{-1}$  and  $T$  is the temperature in kelvin [87]. The molar heat capacity at 298 K is  $59.5 \text{ cal mol}^{-1} \text{ } ^\circ\text{C}^{-1}$ .

The heat capacity of RDX in the range from 293–423 K (20–150 °C) can be described by the following linear equation [282]:

$$c_p = 0.235 + 8.43 \times 10^{-4} t$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$  and  $t$  is the temperature in °C.

Heat capacity of RDX with a density of  $1.804 \text{ g/cm}^3$  in the range 310–440 K (37–167 °C) is

$$c_p = 0.232 + 0.00072 t$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$  and  $t$  is the temperature in °C. The mid-range standard deviation was  $0.004 \text{ cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$ .

### Enthalpy of Formation and Heat of Combustion of RDX

The calculated standard enthalpy of formation for RDX as ideal gas in the gas phase is  $191.6 \pm 15 \text{ kJ/mol}$  and the calculated entropy is  $484.5 \pm 15 \text{ J mol}^{-1} \text{ K}^{-1}$  [285].

Table 22 provides a summary of published thermodynamic data for RDX. It is surprising that for a widely used energetic material like RDX the data for enthalpy of formation in the literature differ widely. Even a well-established, experienced agency like NIST on their Chemistry WebBook web site [85] gives just a juxtaposition of various data without the ability to rank their reliability and eliminate the less reliable ones. Along the same line, we can give only a collection of data with no verification. Most of these data were derived from heat of combustion measurements. It seems that

**Table 22:** Standard enthalpy of formation of RDX.

| Phase       | SI units  |        | Other units |        | References |
|-------------|-----------|--------|-------------|--------|------------|
|             | kJ/mol    | kJ/kg  | kcal/mol    | cal/g  |            |
| Solid       | +66.9     | +301.4 | +16.0       | +72    | [133]      |
|             | +61.55    | +277.1 | +14.71      | +66    | [241]      |
|             | +61.3     | +276.1 | +14.66      | +66    | [235]      |
|             | +79.1 ± 5 | +356   | +17 ± 1.2   | +76.5  | [87]       |
|             | +61.5     | +276.9 | +14.7       | +66.17 | [286, 287] |
|             | +61.5     | +276.9 | +14.69      | +66.1  | [288, 289] |
| Vapor (gas) | +192      | +864.4 | +45.9       | +206.6 | [290]      |

$$M = 222.1163 \text{ g/mol} = 4.5021 \text{ mol/kg}$$

the amounts of condensate and nitric acid in the condensate are two of the variables responsible for the scatter of data.

### Heat of Combustion of RDX

The heat of combustion of RDX is difficult to determine calorimetrically because the pure compound might explode instead of just burning in an oxygen-filled combustion bomb in a calorimeter. Even if complete combustion is achieved by taming the reaction by addition of diluents with known heats of combustion, collecting the condensate and correcting for the amount of nitric acid in the condensate introduces additional sources of error. Literature data for the upper heat of combustion of RDX (going to liquid water) are summarized in Table 23.

**Table 23:** Isochoric upper heat of combustion of RDX.

| SI units     |           | Other units |       | References |
|--------------|-----------|-------------|-------|------------|
| kJ/mol       | kJ/kg     | kcal/mol    | cal/g |            |
| 2124         | 9562      | 507.5       | 2285  | [291]      |

$$M = 222.116 \text{ g/mol} = 4.5021 \text{ mol/kg}$$

### Heat of Fusion and Solid-State Phase Transitions of RDX

RDX decomposes at the melting point, so it would be difficult to determine the heat of fusion calorimetrically. Domalski and Hearing [293] reported the enthalpy of fusion of RDX as 37.66 kJ/mol (9.00 kcal/mol). The heat of melting can be taken as 33.1 kJ/mol (7.9 kcal/mol or 35.6 cal/g) from Zeman [40]. The heat of fusion of a samples of RDX prepared by the Woolwich process melted at 478.4 K (205.3 °C) and the heat of fusion was  $30.77 \pm 2.69 \text{ kJ/mol}$  ( $7.356 \pm 0.642 \text{ kcal/mol}$ ) [294]. Other sources gave the heat of fusion as  $161 \text{ kJ/kg} = 35.76 \text{ kJ/mol} = 8.547 \text{ kcal/mol}$ .

A publication by Hall [245] gave the heat of fusion of RDX at the m.p. = 478.5 K = 205.4 °C as  $35.65 \pm 0.29 \text{ kJ/mol}$  ( $8.52 \pm 0.07 \text{ kcal/mol}$ ). Processes of solid phase transition, fusion, and decomposition in several nitramines have been investigated using DSC. The values for the temperatures and enthalpy changes  $\Delta H$  are reported in Table 24.

Calculating first-order rate constants for decomposition in the region of the solid → liquid transition of nitramines indicated a “premonitory” effect at temperatures below the melting point. With the exception of RDX (apparent  $E_a = 189 \pm 1.7 \text{ kJ/mol} = 45.2 \pm 0.4 \text{ kcal/mol}$ ), the apparent activation energies for decompo-

Table 24: Heat of solid phase transition, fusion, and decomposition of nitramines.

| 1,3-dinitro-1,3-diazacycloheptane               | DDCHP   | 370                                   | ≈ 23.4       | ≈ 5.6       | ≈ 3.97           | ≈ 0.95      |                   |

Data source: [245]; Subscript legend: t = transition, fus = fusion, dec = decomposition

sition of the nitramines tended to be unrealistically high. This type of behavior with RDX may be related to molecular rotation in the solid state.

When searching for a relationship between bond dissociation energies of the weakest bond in the molecule and the heat of fusion, no unambiguous relationships could be found between the heat of fusion and bond dissociation energies of cyclic nitramines like RDX and HMX [295].

### Heat of Sublimation of RDX

Table 25 is a comparison between published literature enthalpy of vaporization values. The data vary considerably, depending on the method how the vapor pressure data were obtained, depending on the purity of the sample, and depending on the temperature range where the vapor pressure was measured. See also [296].

**Table 25:** Comparison between published literature enthalpy of sublimation values for RDX.

$$M = 222.116 \text{ g/mol} = 4.5021 \text{ mol/kg}$$

#### 12.2.2.9 Molecular Structure of RDX

The chair conformation of  $C_{3v}$  symmetry with the  $\text{NO}_2$  groups in the axial positions was accepted for RDX. The molecular structure of RDX is

The good thermal stability of the compound is partially due to its symmetry.

A study using several different methods, such as IR, Raman, and NMR spectroscopy, dipole moment, and depolarized Rayleigh scattering measurements, and INDO calculations, suggested that the RDX molecule has approximate  $C_{3v}$  symmetry in solution, with some distortion associated with the  $\text{NO}_2$  groups [297]. The ring undergoes rapid interconversion in which the cyclic nitrogens oscillate about the planar ( $sp^2$ ) position. There are numerous computational chemistry studies of the molecular structure of RDX, most of them using density functional theory (DFT) methods. There is not enough space in this book to reference them all. Some of those studies also try to model changes in the molecular structure of RDX crystals as they are compressed in a shock wave and transition to a detonation. For theoretical prediction and interpolation of the density of solid nitramines, see also [11].

### Crystal Structure of RDX

XRD or neutron diffraction is the preferred tool for the investigation of the crystal structure of energetic materials, at atmospheric pressure as well as elevated pressure.

The crystal structure of RDX has been refined from single crystal neutron diffraction data. The compound crystallizes in the orthorhombic space group  $Pbca$ , with  $a = 13.182 \text{ \AA}$ ,  $b = 11.574(2) \text{ \AA}$ ,  $c = 10.709(2) \text{ \AA}$ ,  $Z = 8$ . The molecule consists of alternate  $\text{CH}_2$  and  $>\text{N}-\text{NO}_2$  groups in a puckered ring. The environment of the atoms is essentially tetrahedral, and the  $>\text{N}-\text{NO}_2$  groups are planar. The molecule possesses a plane of approximate mirror symmetry perpendicular to the plane defined by the three carbon atoms.

The unit cell dimensions of  $\alpha$ -RDX at atmospheric pressure are  $a = 1.318 \text{ nm}$ ,  $b = 1.157 \text{ nm}$ , and  $c = 1.071 \text{ nm}$ . The pressure–temperature phase diagram for RDX has been determined up to 573 K and 7.0 GPa using powder XRD, IR spectroscopy, and optical polarizing microscopy, and it was demonstrated that an orthorhombic  $\gamma$ -form is produced above 3.8 GPa at ambient temperature [265]. Several theoretical studies have reproduced the effects of hydrostatic compression on the crystallographic lattice parameters of the  $\gamma$ -form, but in the absence of experimental structural data, these predictions could not be verified.

The crystal structure of the high-pressure phase of  $\gamma$ -RDX, which is stable above 4 GPa at room temperature, was investigated by using IR spectroscopy and powder XRD measurements using a diamond anvil cell [298]. Although  $\gamma$  and  $\alpha$  phases were found to belong to the same space group  $Pbca$ , they exhibited a different crystal packing. The molecular structure of the  $\gamma$  phase exhibited the same conformation as that of the  $\alpha$  phase; however, the torsion angles of  $\text{N}-\text{NO}_2$  changed marginally.

Using a combination of X-ray single crystal and neutron powder diffraction, the crystal structure of the high-pressure  $\gamma$ -form of RDX has been determined at 5.2 GPa and showed that the RDX molecules adopt different conformations compared to the conformation found in the ambient-pressure  $\alpha$ -form [267, 299]. At pressures up to 3.85 GPa, all of the patterns could be refined using the orthorhombic ( $Pbca$ ) structure of the  $\alpha$  modification. High-pressure, single crystal XRD data were processed as

follows:  $\gamma$ -phase  $\text{C}_3\text{H}_6\text{N}_6\text{O}_6$ ,  $M = 222.12$ , orthorhombic, space group  $Pca2_1$ , unit cell parameters  $a = 12.565009 \text{ \AA}$ ,  $b = 9.4769(6) \text{ \AA}$ ,  $c = 10.9297(9) \text{ \AA}$ ,  $V = 1301 \text{ \AA}^3$ ,  $P = 5.20(5) \text{ GPa}$ ,  $Z = 8$ ,  $\rho_c = 2.267 \text{ g/cm}^3$ . Across the  $\alpha \rightarrow \gamma$  transition, a 3% decrease in unit cell volume was observed. This is slightly larger than previously reported, but presumably reflects the higher precision of the lattice parameters obtained in the more recent study.

Whereas positions and intensities of diffraction peaks yield information on the crystal structure, peak profiles (e.g., width at half-height) are related to the real structure determined by crystallite sizes, shapes, and microstrains. The size/strain broadening of RDX XRD peaks was measured and interpreted based on crystal geometry [300].

A study of the crystal structure of the highly metastable  $\beta$ -form of RDX showed that the molecules adopt different conformations compared to the  $\alpha$ -form and that, contrary to previous reports, the  $\beta$ -form obtained at ambient pressure is not the same form as that obtained at elevated temperatures and pressures [301–303].

The other modification of RDX,  $\epsilon$ -RDX, a high-pressure, high-temperature form of RDX, has been structurally characterized using a combination of diffraction techniques, and a sample of this form has been successfully recovered at down to ambient pressure [304]. Table 26 is a compilation of the unit cell parameters of the four known polymorphs of RDX.

**Table 26:** Crystal structure and unit cell parameters of the four known polymorphs of RDX.

| Polymorph<br>Space group | $\alpha$ -RDX<br><i>Pbca</i> | $\beta$ -RDX<br><i>Pca2<sub>1</sub></i> | $\gamma$ -RDX<br><i>Pca2<sub>1</sub></i> | $\epsilon$ -RDX<br><i>Pca2<sub>1</sub></i> |
|--------------------------|------------------------------|-----------------------------------------|------------------------------------------|--------------------------------------------|

Note: Data for the  $\alpha$ - and  $\epsilon$ -forms refer to RDX-d6, and data for the  $\beta$ - and  $\gamma$ -forms refer to RDX-h6. Data were collected at 5.2 GPa for the  $\gamma$ -form.

Data source: [304]

### Computational Chemistry Calculations of RDX Properties

There are numerous computational chemistry calculations to predict properties and performance of RDX and similar molecules as explosives. The following is only a short summary of this literature. Calculations were performed to predict density of nitramine crystals [15], gas phase enthalpies of formation [305], and other properties.

Volume dependence of the total energy and vibrational properties of crystalline RDX were calculated using the density functional theory (DFT) [306]. For this molecular crystal, properties calculated with a generalized gradient approximation to the exchange-correlation energy differed drastically from experimental values. It was assumed that this discrepancy arose from the inadequacy in treating weak van der Waals interactions between molecules in the crystal, and an empirical van der Waals correction to DFT was shown to accurately account for the dispersion effects for the RDX crystal, while incurring little additional computational effort. The nonempirical van der Waals density functional method also provided an accurate description of the van der Waals corrections but with orders-of-magnitude more computation steps.

#### 12.2.2.10 Dipole Moment and Dielectric Constant of RDX

The dielectric constant of RDX at 298 K and 5 MHz is 3.14.

#### 12.2.2.11 Optical Properties of RDX

##### IR Spectra of RDX

Two IR spectra of RDX, unfortunately some of only poor quality of reproduction, are shown in Figure 11 and 12.

The transmission IR and the laser excited Raman spectra of polycrystalline RDX have been measured in the range of 40 to 4000  $\text{cm}^{-1}$  [307]. To aid assignments in the spectral region of 400 to 4000  $\text{cm}^{-1}$ , the spectra of two types of  $^{15}\text{N}$ -labeled samples and the solution spectra in different solvents were also recorded (Figure 13). From these data, it was possible to assign many of the observed bands to intramolecular modes of the RDX molecule. The Raman active lattice modes also were resolved and found to be comparable to the lattice mode frequencies in solid cyclohexane.

In a similar project, it was possible to make unambiguous vibrational band assignments in vibrational spectra of  $\alpha$ -RDX with the use of  $^{13}\text{C}$  and  $^{15}\text{N}$  (on ring) enriched RDX isotopologues [308]. Vibrational spectra were collected using Raman and

**Figure 11:** Infrared spectrum of RDX. (Reproduced and modified from [81])

**Figure 12:** Infrared spectrum of RDX. (Reproduced and modified from [244].)

**Figure 13:** Transmission vs. frequency traces of the KBr pellet IR spectra of RDX between 400 and 1700  $\text{cm}^{-1}$  of (a) Nitro group labeled RDX (b) Ring labeled RDX (c) Unlabeled RDX. (Reproduced and modified from [307].)

IR spectroscopy in the solid state and compared to the results of *ab initio* normal mode calculations which were performed using density functional theory (DFT). The calculated isotopic frequency shifts, induced by  $^{13}\text{C}$  and  $^{15}\text{N}$  labeling, were in very good accordance with measured ones. The changes in vibrational modes associated with the isotopic substitutions were well modeled by the calculation and previous assignments of the vibrational spectra have been revised, especially where the exact nature of the vibrational modes had been either vague or contradictory.

The optical constants of RDX and HMX were determined using KBr pellet-FTIR transmission spectrometry in conjunction with dispersion theory, which accounts for radiation scattered by the KBr pellets [309]. Advantages of the FTIR/KBr pellet method are that optical constants can be obtained even in strongly absorbing regions with sufficient dilution and fine enough particles and they can be obtained over a broad spectral range. Optical properties of RDX and HMX were obtained from 2.5 to 18  $\mu\text{m}$  using scattering-corrected KBr pellet-FTIR transmission spectrometry. Absorption index ( $k$ ) was measured directly and refractive index ( $n$ ) was deduced using dispersion theory. At 10.6  $\mu\text{m}$  ( $\text{CO}_2$  laser wavelength) the absorption coefficients were  $2800\text{ cm}^{-1}$  for RDX and  $5670\text{ cm}^{-1}$  for HMX. The refractive indices in the visible range were 1.594 for RDX and 1.597 for HMX.

#### 12.2.2.12 Raman Spectra of RDX

Fourier transform Raman (FTR) spectroscopy employing near-IR laser radiation at 1.06  $\mu\text{m}$  as the scattering source has been used to obtain Raman spectra of RDX and propellant formulations containing RDX, as shown in Figure 14, [310, 311].

**Figure 14:** Raman spectrum of RDX. (Reproduced and modified from [310].)

Raman spectra of RDX, HMX, and 30 other explosive materials to be used for the design of an explosive detection device were recorded. The samples were excited with the 1064 nm line from a diode-pumped Nd:YAG laser [312].

A comparison of the very similar Raman spectra of RDX and HMX is shown in Figure 15. Note that the two spectra have different scale expansions [312, 313].

**Figure 15:** Raman spectra of RDX (*bottom*) and HMX (*top*). (Republished and modified from [312], with permission of ©1995 Elsevier; permission conveyed through RightsLink.)

Raman spectroscopy has been used to investigate the  $\alpha \rightarrow \beta$  solid–solid phase transition of RDX in real time [314]. The thermal conversion of  $\alpha \rightarrow \beta$  at atmospheric pressure occurred at 477 K. Temperature-induced spectroscopic changes in the Raman spectrum of  $\alpha$ -RDX, such as peak shifting and broadening and disappearance of spectral bands confirmed the phase transition. For the interpretation of the experimental results, the structural and spectral characteristics of  $\alpha$ - and  $\beta$ -RDX have been studied by performing density functional theory (DFT) calculations for energies, geometries, vibrational frequencies, and NMR shielding constants. The theoretical data, using DFT approximation, and experimental results were consistent with each other. The results from these experiments showed that once  $\beta$ -RDX is formed by heating at slow rates, crystal transformation occurs near the melting point and no reversible change in the symmetry can be observed. The differences in the Raman spectra of both solid phases are evident and persistent. In addition, the results of calculated and experimental NMR chemical shifts ( $^{13}\text{C}$  and  $^{15}\text{N}$ ) confirmed the agreement between the  $\alpha$  conformer and the  $\beta$ -RDX structure.

### Refractive Index of RDX

The refractive index  $n_D^{20}$  of  $\alpha$ -RDX is 1.578, that of  $\beta$ -RDX is 1.597 and that of  $\gamma$ -RDX is 1.602. The molar refraction is 41.4.

### 12.2.3 Chemistry of RDX

The oxygen balance of RDX is  $-21.6\%$  for combustion to  $\text{CO}_2$  and thus it should not be designated as an “oxidizer” when added to CMDB propellants because it is thus substantially underoxidized. The nitrogen content is  $37.84 \text{ mass-\% N}$ . RDX is underoxidized, but a powerful explosive and a very useful ingredient for CMDB solid propellants. RDX would be stoichiometrically balanced if one assumed that combustion proceeds only to CO and not all the way to  $\text{CO}_2$ :

#### 12.2.3.1 Analysis of RDX

Analytical methods for RDX are summarized in [315]. Commercial grades of RDX were found to contain  $0.2\%$  HMX.

#### 12.2.3.2 Thermal Decomposition of RDX

RDX is unique among the heterocyclic nitramines in that it has good thermal stability. The kinetics of RDX decomposition have been investigated exhaustively, be it either to explain limits to its thermal stability or in search of related compounds with even better thermal stability and higher performance. The study of thermal decomposition was done either experimentally or by calculations of its molecular structure, trying to identify the weak link in the molecule where the molecule starts breaking apart when heated. Several of the studies have been done looking at both RDX and HMX and comparing properties of the two. Because these publications can be cited either here, at HMX, or at both locations, there is some overlap and redundancy between these two sections in this book.

### Experimental Studies of RDX Decomposition

There are many thermal analysis techniques as well as specialized thermal techniques that are used to characterize explosives, including pressure measurement techniques, gaseous product analysis, DTA, DSC, TGA, combined TGA-DTA, and all have been applied to the study of the thermal stability of RDX and similar energetic materials [316].

The thermal decomposition of energetic materials is closely related to their strand burning rates. For an evaluation of kinetic data of RDX decomposition in combustion waves in a strand burner, the following data for RDX were taken from the literature: heat capacity  $c_p = 1.59 \text{ kJ kg}^{-1} \text{ K}^{-1}$  ( $0.38 \text{ cal g}^{-1} \text{ }^\circ\text{C}^{-1}$ ), thermal conductivity  $\lambda = 2.3 \times 10^{-2} \text{ kJ s}^{-1} \text{ m}^{-1} \text{ K}^{-1}$  ( $5.6 \times 10^{-4} \text{ cal s}^{-1} \text{ cm}^{-1} \text{ }^\circ\text{C}^{-1}$ ), and density  $\rho = 1.75 \text{ g/cm}^3$ , respectively. Thermal conductivity data for RDX and other solid rocket propellant oxidizers and binder materials are available from [282]. According to DSC studies, heat of reaction of RDX decomposition in the melt is equal to  $1080 \text{ kJ/kg}$  ( $258 \text{ cal/g}$ ) [317].

A comparison of RDX decomposition kinetics for the molten substance, shown in Figure 16, is based on kinetic parameters of RDX decomposition derived from

**Figure 16:** Comparison of kinetic parameters of the leading reaction on RDX combustion and decomposition in the melt. RDX combustion (1) Sinditskii et al. [252], (2) Rogers and Daub [249], (3) Robertson [318], and (4) Oxley et al. [38]. (Republished and modified from [252], with permission of ©2009 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

a combustion model for the temperature range 610–800K, which is above the temperature range accessible by DSC, and on the rate equation

$$k = 10^{15.92} \cdot \exp(-20890/T)$$

where  $k$  is the rate constant in  $\text{s}^{-1}$  and  $T$  is the temperature in kelvin. This rate equation is in good agreement with the experimental rate constants of RDX decomposition in the melt obtained at lower temperatures.

During a study of isothermal rates of RDX and other explosives by DSC, it was observed that several compounds gave two first-order curves with two different slopes at each temperature. The second curve was normally smaller than the first, and the rate constant obtained from the second curve was larger. The relative sizes of the two parts of the rate curve could be varied by changing the volume of the sample cell. The working hypothesis that seemed best to explain the observations was that the “tail” of the DSC rate curve was the result of decomposition in the vapor phase [249].

The decomposition of liquid RDX and HMX follows a unimolecular rate equation. The decomposition of RDX in dicyclohexyl phthalate or trinitrotoluene as solvent/diluent had a frequency factor approaching the normal value. A more concentrated solution of RDX decomposed faster than the dilute solutions. This fact and the anomalous frequency factor for the pure liquid were explained in terms of a chain reaction of short length with a temperature-dependent chain length [318]. The results on the decomposition of RDX showed that in solutions of dicyclohexyl phthalate or trinitrotoluene (TNT) the decomposition exhibited a unimolecular behavior, whereas neat RDX and HMX show an effect of neighboring molecules. Post-test analysis of the gases evolved in these experiments showed the presence of NO, N<sub>2</sub>O, N<sub>2</sub>, CO, CO<sub>2</sub>, CH<sub>2</sub>O, and H<sub>2</sub>O. This early work provided the initial evidence that the decomposition of RDX and HMX occurs by transfer of an oxygen atom from the NO<sub>2</sub> group to the CH<sub>2</sub> group.

High-pressure elevated-temperature studies of HMX and RDX indicated that during chemical decomposition (and perhaps melting) the electrical resistance rapidly decreased about three orders of magnitude, attained a minimum, and thereafter generally increased with increasing temperature [319]. Pressure studies of these materials from about 10 to 40 kbar did not show a monotonic trend regarding the pressure dependence of the temperatures of most of the electrical anomalies, due to complex kinetic behavior.

The mechanisms that are used to explain the decomposition of RDX and HMX are based on results from simultaneous TGA modulated beam mass spectrometry (STMBMS) and time-of-flight (TOF) velocity-spectra measurements [320]. These methods are used to identify the decomposition products and to determine their formation rates as a function of time during the decomposition of the samples. Both nitramines form H<sub>2</sub>O, N<sub>2</sub>O, CH<sub>2</sub>O, NO, and CH<sub>3</sub>NHCHO during decomposition. RDX forms NO<sub>2</sub> and hydroxy-*s*-triazine, products associated with N—N bond breaking, whereas HMX forms C<sub>2</sub>H<sub>6</sub>N<sub>2</sub>O, CO, and a nonvolatile residue.

The effects of very high pressure on the thermal decomposition kinetics, chemical reactivity, and phase behavior of RDX, HMX, and nitromethane have been studied by a combination of measurement techniques in conjunction with a high pressure diamond anvil cell [321]. These techniques included (1) FTIR spectroscopy, (2) EDAX, (3) optical polarizing microscopy, and (4) Raman scattering. Studies were generally limited to the region where decomposition rates could be measured within reasonable laboratory time, i.e., below 10 GPa and 573 K. The pressure-temperature phase diagram for RDX was determined to 373 K and 7.0 GPa, delineating the stability fields of three solid phases,  $\alpha$ ,  $\beta$ , and  $\gamma$ , and the liquidus. The  $\alpha$  and  $\beta$  phases of RDX were found to thermally decompose, while the  $\gamma$  phase transformed to either  $\alpha$  or  $\beta$  before reaching decomposition temperatures. The decomposition rate of  $\alpha$  phase was found to increase with increasing pressure suggesting a bimolecular-type mechanism. Conversely,  $\beta$  HMX decomposition rates decreased with increasing pressure suggesting a unimolecular-type reaction mechanism.

### Slow Thermal Decomposition of RDX

As part of a multiyear, Multidisciplinary University Research Initiative (MURI) aimed at a better understanding of combustion instability in solid propellant rocket motors, the rates of decomposition and the burning rates of RDX and many other propellant ingredients have been investigated, and models to interpret the experimental results were established. Several of the publications referenced in that report give a good introduction into the mechanisms for RDX decomposition and are repeated here.

Numerous authors have investigated the rates and mechanisms of decomposition of RDX and HMX under slow heating conditions. The thermal decomposition of RDX was investigated in a static system below its melting point at 468 K (195 °C) [322]. The initial decomposition of RDX takes place in the vapor phase. Hydroxymethyl formamide and polymeric materials formed from hydroxymethyl formamide have been shown to be major products. These comparatively low molecular weight materials are highly hydrogen bonded liquids of low volatility which subsequently act as a solvent for decomposing RDX. Nitrogen, due to its effect on the rate of diffusion of RDX vapor away from the crystal surface, was shown to have a rate retarding effect. Other decomposition reaction products, such as formaldehyde, hydroxymethyl formamide, methylene diformamide, and 1,3,5-trinitrobenzene were all shown to enhance the reaction rate [323]. Different initial steps in the mechanisms were indicated for the gas phase and solution phase decompositions.

A review of the ignition and combustion chemistry of HMX and RDX came to the conclusion that direct diagnostic techniques have not yet been invented for subsurface (condensed-phase) or heterogeneous (gas–solid) processes during deflagration or energetic materials and sophisticated flame diagnostic techniques have not yet provided species concentration profiles in fast reactions [324]. Consequently, current knowledge of the combustion (and ignition) chemistry of these propellants comes from indirect sources, such as thermal decomposition experiments or isothermal gas-phase kinetic measurements. A new hypothesis was presented which tried to account for the phase-dependent decomposition rate constants of propellant molecules.

A very useful tool for identifying decomposition reactions of propellant ingredients is the simultaneous thermogravimetric modulated beam mass spectrometry (STMBMS) technique. This instrument allows the rate of selected gas phase product formation to be measured as a function of time and temperature and was applied to the study of the decomposition of RDX and other energetic materials [320, 325]. The results of the STMBMS analysis showed that RDX and HMX have similar decomposition mechanisms as well as similar degradation products [326].

Through the use of STMBMS measurements, TOF mass spectrometry velocity-spectra analysis, and  $^{13}\text{C}$ ,  $^{15}\text{N}$ , and  $^{18}\text{O}$  labeled analogues of RDX, the thermal decomposition products of RDX have been identified as  $\text{H}_2\text{O}$ ,  $\text{HCN}$ ,  $\text{CO}$ ,  $\text{CH}_2\text{O}$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$ ,  $\text{H}_2\text{NCHO}$ ,  $\text{NO}_2$ ,  $\text{HONO}$ , oxy-*s*-triazine (OST), and 1-nitroso-3,5-dinitrohexahydro-*s*-triazine (ONDNTA), and all of their gas formation rates have been measured as a function of time [327]. From these results, the primary reaction pathways that

control the decomposition of RDX in both the solid and liquid phases have been identified. Four primary reaction pathways control the decomposition of RDX in the liquid phase between 473 and 488 K (200 and 215°C). Two pathways are solely first-order reactions in RDX. One produces predominantly OST and NO, and accounts for approximately 30% of the decomposed RDX; the other produces predominantly  $\text{N}_2\text{O}$  and  $\text{H}_2\text{CO}$  with smaller amounts of  $\text{NO}_2$ , CO, and  $\text{H}_2\text{NCHO}$  and accounts for 10% of the decomposed RDX. The third leads to formation of ONDNTA by reaction between NO and RDX, followed by the decomposition of ONDNTA to predominantly  $\text{H}_2\text{CO}$  and  $\text{N}_2\text{O}$ . The fourth reaction pathway consists of decomposition of RDX through reaction with a catalyst that is formed from the products of previously decomposed RDX. The third and fourth reaction channels each account for approximately 30% of the decomposed RDX. In addition to the two forms of OST shown in the schematic below, there may also be an  $\text{N} \rightarrow \text{O}$  oxide structure.

Experiments with solid-phase RDX have shown that its decomposition rate is much slower than that of liquid-phase RDX. ONDNTA is the only product that appears to be formed during the early stages of the decomposition of RDX in the solid phase. As the solid-phase decomposition progressed,  $\text{N}_2\text{O}$  and lesser amounts of  $\text{H}_2\text{CO}$  started to evolve and their rates of evolution increased until products associated with the liquid-phase RDX decomposition appeared and the rate of gas formation of all products rapidly increased. This behavior strongly suggested that the decomposition of

solid RDX occurs through formation of ONDNTA within the lattice. The subsequent decomposition of ONDNTA within the lattice formed  $\text{N}_2\text{O}$  and  $\text{H}_2\text{CO}$ , followed by the dispersion of  $\text{H}_2\text{CO}$  in the RDX, leading to its eventual liquefaction and the onset of the liquid-phase decomposition reactions.

The inter- vs. intramolecular origin of the products formed in the thermal decomposition of RDX was traced by using mixtures of differently labeled isotopologues of RDX [328]. The isotopic analogues of RDX used in the experiments included  $^{13}\text{C}$ ,  $^{15}\text{N}$ , and  $^{18}\text{O}$  labeled analogues of RDX. The fraction of isotopic scrambling and the extent of the deuterium kinetic isotope effect (DKIE) observed for the different thermal decomposition products indicated that isotopic scrambling does not occur for the bond in  $\text{N}_2\text{O}$  and only in small amounts (7%) in the C—H bonds in  $\text{H}_2\text{CO}$ , consistent with an assumed mechanism of their formation through methylene nitramine precursors. An intermediate product, oxy-*s*-triazine (OST) did not undergo isotopic scrambling and its rate of formation exhibited a DKIE of 1.5. These results were consistent with the formation of OST via unimolecular decomposition of RDX. Another product, ONDNTA, was found to be formed with complete scrambling of the N—NO bond, suggesting N—N bond cleavage and a radical recombination process in its formation.

It was observed that the standard DSC thermograms of RDX prepared by the Bachmann process at Holston and the other prepared by the Woolwich process by SNPE in France were noticeably different [294]. The SNPE RDX thermogram exhibited a sharp endothermic event attributed to the RDX melting process at 478.4 K (205.3 °C), which was immediately followed by thermal decomposition. The Holston RDX, on the other hand, exhibited a broad, generally twin-peaked endothermic event that occurred over the temperature range 461–478 K (188–205 °C), which was followed by thermal decomposition. An earlier study [329] of the thermal behavior of mixtures of RDX and HMX at high concentrations (70–100% by weight) of the latter found two endothermic events associated with the mixtures. One was observed at a consistent temperature of 460–461 K (187–188 °C) and the other over the temperature range 472–478 K (199–205 °C) with the temperature increasing as the RDX concentration was increased to a maximum of 30 mass-%. The former event was attributed to RDX melting and the latter to a polymorph transition. A complete temperature/composition melting point diagram is presented in Section 15.2.1.

If RDX is heated beyond its melting point, it is bound to decompose, ignite, and burn. The study of decomposition of liquid RDX would mostly benefit burning rate studies and studies of temperature profiles across the burning surface. However, for assessment of damage suffered by nitramine propellants at temperatures below the melting point of RDX, it is important to look at RDX decomposition in the solid state.

Through the use of simultaneous thermogravimetry modulated beam mass spectrometry, optical microscopy, hot-stage time-lapsed microscopy, and SEM measurements, the physical and chemical processes that control the thermal decomposition of RDX below its melting point in the range 433–462 K (160–189 °C) have been examined and identified [330]. Two gas-phase reactions of RDX were predominant during

the early stages: One involved the loss of HONO and HNO and led to the formation of  $\text{H}_2\text{O}$ , NO,  $\text{NO}_2$ , and oxy-*s*-triazine (OST) or *s*-triazine. The other involved the reaction of NO with RDX to form  $\text{NO}_2$  and 1-nitroso-3,5-dinitrohexahydro-*s*-triazine (ONDNTA), which subsequently decomposed to form a set of products of which  $\text{H}_2\text{CO}$  and  $\text{N}_2\text{O}$  were the most abundant. Products from the gas-phase RDX decomposition reactions, such as ONDNTA, deposited themselves on the surface of the cooler RDX particles and led to the development of a new set of reaction pathways that occurred on the surface of the RDX particles. An orange-colored nonvolatile residue (NVR) film was seen on the surface of the RDX particles. The NVR film was a nonstoichiometric and dynamic material, which reacted directly with RDX and ONDNTA. The competition between reaction of the dynamic NVR with RDX and its own thermal decomposition manifested itself in a rapid increase in the rate of evolution of the NVR decomposition products as the amount of RDX remaining in the sample neared depletion. The reactions between the NVR film and RDX on the surface of the RDX particles led to a localized environment that created a layer of molten RDX on the surface of the particles where reactions associated with the liquid-phase decomposition of RDX occurred. The combination of these reaction processes led to an acceleration of the reaction rate in the later stage of the decomposition process and created an apparent reaction rate behavior that has been referred to as autocatalytic in many previous studies of RDX decomposition.

The common degradation products for both RDX and HMX observed via STMBMS were  $\text{N}_2\text{O}$ ,  $\text{H}_2\text{CO}$ , NO,  $\text{H}_2\text{O}$ , and  $\text{CH}_3\text{NHCHO}$ . Experiments were also carried out on isotopically labeled materials in order to gain additional mechanistic information about which reaction products arise from labeled functional groups in the starting material. Evidence suggested that the first observable product is  $\text{N}_2\text{O}$ . Detecting the degradation products during decomposition is vital because it allows one to determine the specific bonds that are breaking first as well as the order in which the breakage occurs. From this data, one can make kinetic assignments to specific bonds, which aids in determining the overall degradation mechanism. Since  $\text{N}_2\text{O}$  is the first observable product, this suggested that the N—N bond is the weakest in the molecule and that approximately 199 kJ/mol (47.5 kcal/mol) is needed to begin decomposition at this site. See also [320, 331].

Although the activation energies for the liquid state decomposition of RDX have been reported in a number of studies, none of them addressed the dependence of the activation energy on the extent of conversion, either under an assumption of first-order kinetics or by using Kissinger's method. Activation energies reported up to the year 2000 ranged from 125 to 282 kJ/mol, depending on the instrumental method and the data reduction method used.

The thermal decomposition of RDX has been studied by TGA and DSC, and activation energies as a function of the extent of conversion,  $\alpha$ , have been determined by model-free isoconversional analysis of these data [332]. In open pans, evaporation is a prevalent process with an activation energy of  $\sim 100$  kJ/mol. TGA and DSC curves were measured for RDX in open pans or pierced lid pans and DSC curves were mea-

sured in closed pans at heating rates ranging from 7.5 to 20 °C/min. In the TGA, the pierced lid method gave more reproducible curve shapes. The major TGA mass loss occurred between 443 and 533 K (170 and 260 °C). A superposition of three DSC curves obtained in open, pierced, or closed pans clearly showed the contribution of evaporation to the endothermic part of the curves. Literature reports and the TGA and DSC data suggested that the liquid state thermal decomposition of RDX involves three major steps: vaporization, liquid phase decomposition, and gas phase decomposition. Confining the system in either a pierced pan or a closed pan promoted liquid state decomposition of RDX that occurred with an activation energy of ~200 kJ/mol, which suggests scission of an N—N bond as the primary decomposition step [333]. In such a confined environment, gas phase decomposition is a competing channel with an activation energy estimated to be ~140 kJ/mol. In a closed pan, RDX generated a heat release of ~500 kJ/mol that was independent of both the heating rate,  $\beta$ , and the mass.

1-Nitroso-3,5-dinitro-*s*-triazine (ONDNTA) is an intermediate in the decomposition of RDX. In order to resolve the multistep process of RDX decomposition into individual reactions, the thermal decomposition of ONDNTA was investigated using the same methods previously used for RDX [334].

The slow thermal decomposition of RDX in a DTA starts with the onset of exotherm at 488 K and culminates at 508 K. The off-gassing of RDX decomposition products measured with a thermoconductivity GC detector (dashed line) was superimposed on the DTA trace (solid line) of RDX as shown in Figure 17. The melting endotherm is immediately followed by a decomposition exotherm. Gas evolution detected by the thermoconductivity bridge below the melting point is primarily sublimation and not decomposition.

**Figure 17:** Differential thermal analysis of RDX decomposition. (Reproduced and modified from [241].)

A sample of RDX prepared by the Woolwich process had a melting point of 478.43 K (205.28 °C) and immediately following the melting endotherm, it had a strong maximum exotherm at 499.51 K (226.36 °C) (Figure 18).

Decomposition of  $\gamma$ -RDX under high pressure-high temperature conditions was examined to elucidate the reactive behavior of RDX crystals [335]. Vibrational spectroscopy measurements were obtained for single crystals in a diamond anvil cell at pressures from 6 to 12 GPa and temperatures up to 600 K. Global decomposition rates, activation energies and activation volumes at several pressures and temperatures below the pressure-temperature point for the  $\gamma$ -RDX decomposition were obtained. Similar to  $\epsilon$ -RDX, but in contrast to  $\alpha$ -RDX, it was found that pressure decelerated the decomposition of  $\gamma$ -RDX. The decomposition deceleration with pressure in the  $\gamma$ -phase can be attributed to pressure-inhibited bond homolysis step(s). The main decomposition species were identified as  $\text{N}_2\text{O}$ ,  $\text{CO}_2$ , and  $\text{H}_2\text{O}$ , in accordance with the species reported for the  $\alpha$ -phase decomposition at high pressures. The  $\gamma$ -phase plays a key role in RDX decomposition at pressure-temperature conditions relevant to shock wave initiation.

### Rapid Thermal Decomposition of RDX

As part of a multiyear, Multidisciplinary University Research Initiative (MURI) aimed at a better understanding of combustion instability in solid propellant rocket motors, the rates of rapid decomposition and the burning rates of RDX and many other propellant ingredients have been investigated, and models to interpret the experimental

results were developed [336]. Several of the publications referenced in that report give a good introduction into the mechanisms for RDX decomposition and are included in the discussion here.

The combustion-like pyrolysis chemistry of energetic materials liberates products which then diffuse into the flame zone. High rate pyrolysis studies, which emphasize the condensed phase, can be grouped according to the method of heating: infrared laser and hot surface. A number of variations of these two methods have been developed. CO<sub>2</sub> lasers can be used in the pulsed or continuous wave mode to decompose the surface layer at heating rates on the order of 10<sup>7</sup> K/s. Two advantages of this method are that very fast heating can be achieved and chemical diagnostic techniques can be used in conjunction to determine the products that are formed. A disadvantage is that independent pre-test selection of the heating rate and final temperature is not possible so that kinetic determinations are difficult.

The flame structure of RDX under laser-assisted combustion conditions was studied to better understand related chemical and physical processes in the gas phase [337]. Experiments were conducted under pressures from 10 to 303 kPa (0.1 to 3 atm) with heat fluxes of 50 to 600 W/cm<sup>2</sup>. Gaseous products were extracted through the use of quartz microprobes and analyzed by a triple quadrupole mass spectrometer (TQMS). Temperature profiles were measured using microthermocouple techniques to investigate reaction zones in RDX flames. Flame behavior was observed using a high-magnification video system. Major species in RDX flames were identified as H<sub>2</sub>, H<sub>2</sub>O, HCN, H<sub>2</sub>CO, NO, HNC, N<sub>2</sub>O, and NO<sub>2</sub> at low masses ( $m/z \leq 47$ ). In addition to these species, H<sub>2</sub>C=NH with  $m/z = 29$  was found to exist in the near-surface reaction zone as an important minor species. Higher molecular weight species were found at  $m/z$  values of 47, 54, 56, 70, 81, and 97 and were identified as HONO, C<sub>2</sub>H<sub>2</sub>N<sub>2</sub>, C<sub>2</sub>H<sub>4</sub>N<sub>2</sub>, C<sub>2</sub>H<sub>2</sub>N<sub>2</sub>O, C<sub>3</sub>H<sub>3</sub>N<sub>3</sub>, and C<sub>3</sub>H<sub>3</sub>N<sub>3</sub>O, respectively. Increasing heat flux and decreasing pressure stretched out the reaction zones and were useful for investigating reactions near the deflagrating surface. The decomposition of RDX at the surface showed evidence of the two competing branch reactions into H<sub>2</sub>CO + N<sub>2</sub>O and HCN + HONO, as well as two subsequent reactions:

and

With the consideration of the four reactions, the branching ratio for the two decomposition pathways of RDX was estimated to be about 2 : 1.

When examining the impact of laser radiation on propellant surfaces, three distinct categories of laser-induced behavior were observed: laser-induced pyrolysis (LIP) characterized by decomposition without stable surface regression; laser-induced regression (LIR); and laser-assisted combustion (LAC) [338]. The latter two categories were characterized by stable regression of the surface, but with a luminous flame only

observed for LAC. Under LIP conditions, RDX exhibited a thick melt layer with considerable bubbling. Gas species within a bubble were measured, with the most abundant species being  $\text{CH}_2\text{O}$ ,  $\text{H}_2\text{O}$ ,  $\text{NO}_2$ , and  $\text{N}_2\text{O}$ . Species profiles for RDX at 0.5 and 1.0 atmospheres under LAC conditions were measured. Reaction of  $\text{CH}_2\text{O}$  and  $\text{NO}_2$  occurred directly above the surface followed by a final luminous flame due to reaction of HCN, NO, and  $\text{N}_2\text{O}$ . The kinetic model for RDX decomposition was in excellent agreement between model and experimental species profiles.

A gas phase molecular beam laser pyrolysis experiment provided convincing evidence that a major decomposition route of RDX is the concerted depolymerization of gas phase RDX to form three molecules of methylenenitramine,  $\text{H}_2\text{C}=\text{NNO}_2$ . Infrared multiphoton dissociation (IRMPD) of RDX in a molecular beam was used to investigate the mechanism of RDX thermal decomposition [339]. A beam of molecules was crossed by a pulsed TEA  $\text{CO}_2$  laser and velocity distributions of the various products were measured by the time-of-flight (TOF) technique as a function of the laboratory angle using a mass spectrometric detector. In contrast to the conventional view of simple bond rupture through loss of  $\text{NO}_2$  as the dominant primary channel in RDX decomposition, it was found that the dominant primary channel is concerted symmetric triple fission to produce three  $\text{H}_2\text{C}=\text{NNO}_2$  fragments which subsequently undergo secondary concerted dissociation to produce HCN,  $\text{H}_2\text{CO}$ , HONO (or  $\text{HNO}_2$ ), and  $\text{N}_2\text{O}$ . A total of two primary and four secondary dissociation channels were observed. Concerted reactions predominate over simple bond rupture not only in the number of channels (four vs. two), but also in the amount of products. A fair amount of translational energy release through concerted reaction channels was observed, which was significant for an explanation of the energies of RDX decomposition. Theoretical studies of the reactions leading to the autoignition of RDX vapor may be able to predict the point of runaway reaction in a cook-off situation [41, 340, 341].

Instead of aiming the laser at a solid block of RDX, it may be useful to incrementally pyrolyze only thin film layers. One can use a single laser pulse to heat a film of RDX sandwiched between two transparent windows at 77 K [342, 343]. The film can be heated to 1000 K in 35  $\mu\text{s}$  and by the use of FTIR spectroscopy, it was demonstrated that cleavage of the N— $\text{NO}_2$  bond is the initial step in fast decomposition of RDX.

Thin film laser pyrolysis a new experimental technique for detecting initial reaction products of thermal decomposition under conditions that simulate rapid combustion [344]. The apparatus consisted of a vacuum chamber with an  $\text{LN}_2$ -cooled cold finger, a quartz window, two CsI windows for IR transmission, a modified Knudsen oven containing approximately 10 mg of propellant. When the oven is heated to approximately 120 °C, the propellant is vaporized and condensed as a thin film (10  $\mu\text{m}$  or less) on the cold optical window. The laser is fired through the quartz window so that the thin film is irradiated with the pulsed output of a line-tunable ( $944\text{ cm}^{-1}$ )  $\text{CO}_2$  laser to heat them from 77 K to approximately 1000 K in 35  $\mu\text{s}$ . The films are then cooled back to 77 K in a few milliseconds by heat conduction into the film support. Then the IR ab-

sorption of the pyrolyzed residue can be measured by an IR spectrophotometer. This cycle of laser pyrolysis and infrared spectroscopy can be repeated on the same sample at successively higher laser fluence (to about  $4.7 \text{ J/cm}^2$ ). At higher fluence, additional reaction products were formed due to subsequent steps in the thermal decomposition mechanism. These products included NO,  $\text{N}_2\text{O}$ , HCN, and  $\text{CO}_2$ . Results of numerous experiments on RDX films showed that the initial step in the thermal decomposition mechanism under these conditions is unimolecular scission of a single N—N bond in the condensed phase. This reaction formed nitrogen dioxide, which was detected in its condensed dimerized form, dinitrogen tetroxide.

Experimental results from a CW  $\text{CO}_2$  laser pyrolysis/MS apparatus were compared to predictions from a one-dimensional model of such an apparatus [345]. In the experiments, a microprobe/triple quadrupole mass spectrometer system was used to measure quantitative gas-phase species profiles and a high-magnification video system was used to observe surface behavior and flame structure. Gas-phase species evolved from the surface and also inside a bubble were measured. The species identified at the surface were HCN,  $\text{NO}_2$ ,  $\text{H}_2\text{O}$ , NO, CO,  $\text{N}_2\text{O}$ ,  $\text{N}_2$ , and  $\text{H}_2$ , but no  $\text{CO}_2$  was found at the surface. Formaldehyde may have been present, but it could not be unambiguously identified. Species mol fractions measured at 1.0 atm and a heat flux of  $4 \text{ MW/cm}^2$  were used as input to a one-dimensional model along with a temperature profile obtained from the literature for similar experimental conditions. In order to obtain reasonable agreement between the model and the experiments for stable species, undecomposed RDX vapor had to be added to the initial species for the model calculations. However, even with this addition, the profiles for OH and NH did not match data available in the literature. The data were particularly helpful for comparing the products of pyrolysis to those from laser-assisted combustion. Hot surface or filament heating methods offer the advantage of fast pyrolysis with independent control over the heating rate and final temperature. The disadvantage is that the heating rates are lower than are possible with the  $\text{CO}_2$  laser. The most widely applied method of this type is T-jump/FTIR spectroscopy where the sample is a thin coating on a rapidly heated platinum wire or ribbon [346].

The decomposition of RDX was modeled as part of a more complex model of the platinum filament, energetic substance sample and surroundings as a system. The model showed that heating rates up to  $600 \text{ K/s}$  should be achievable while stopping and holding at a known and adjustable target temperature [347]. The predicted time elapsed to the point of rapid energy release by decomposing RDX agreed with measurements. The control voltage of the filament can be recorded simultaneously with rapid-scan FTIR spectra of the evolved products to obtain thermochemical information, product sequencing, and formation rates. Catalytic effects of the platinum filament have been shown to be negligible.

An alternate method used RDX samples confined in a rapidly heated cavity in place of the open filament. This approach improved the heat transfer to the sample but

sacrificed the opportunity to detect the earliest quenched products [348, 349]. T-Jump/FTIR spectroscopy has provided valuable mechanistic information, for example, on RDX and HMX [350].

*In situ*, rapid-scan FTIR spectroscopy in conjunction with the IR absorption intensities was used to construct concentration-time profiles for the gaseous products from thermolysis of RDX and HMX [351]. The pyrolysis cell was capable of attaining rapid heating rates (8–200 K/s) at various gas pressures (0.33 kPa–6.8 MPa = 0.048–1000 psi) and was an attempt to simulate, insofar as possible, combustor conditions. NO<sub>2</sub> was the predominant initial gas product from RDX and, along with HCN, from HMX. NO<sub>2</sub> rapidly diminished with time owing to its participation in secondary reactions. NO was a minor initial product, if it was present at all, but rapidly became a major product owing to secondary reactions. *Cis*- and *trans*-HONO were clearly present initially. Other species observed were N<sub>2</sub>O, H<sub>2</sub>CO, CO, CO<sub>2</sub>, H<sub>2</sub>O, and HNCO. Substantial sublimation of RDX occurred at low pressure resulting in the dominance of gas-phase decomposition (products derived from N–N bond rupture). Above atmospheric pressure, a crossover occurs from largely gas-phase to largely heterogeneous condensed phase decomposition reactions (products derived from C–N bond rupture). Therefore, condensed phase reactions must be involved along with gas-phase reactions when discussing nitramine decomposition under rocket motor conditions.

The decomposition characteristics of liquid-phase RDX were studied using FTIR spectroscopy of evolved gas-phase species from rapid thermolysis and of the condensate and residue formed from the decomposition, as well as time-of-flight mass spectrometry of the evolved gas-phase species [352, 353]. The sub-milligram sample was heated at rates of about 2000 K/s to a set temperature where decomposition occurred under isothermal conditions. Since RDX melts at around 478 K (205 °C), decomposition studies were conducted at temperatures ranging from 538 to 578 K (265 to 305 °C). Species detected by FTIR spectroscopy included CO, CO<sub>2</sub>, NO, N<sub>2</sub>O, NO<sub>2</sub>, *cis*-HONO, *trans*-HONO, HNCO, H<sub>2</sub>CO, HCOOH, HCN, 1,3,4-oxadiazole (*m/z* = 70), oxy-*s*-triazine (*m/z* = 97), and RDX. A decomposition mechanism dealing with the early liquid-phase decomposition and reactions of RDX was postulated based on the acquired experimental data and thermochemical analysis.

### Intermediates in the Thermal Decomposition of RDX

Electron paramagnetic resonance (EPR) provides direct observation of the concentrations of free radicals formed in the initial stages of decomposition processes, and the characteristic EPR spectra may provide identification of the observed species. The combined EPR information can then be compared with proposed mechanisms. Radical species identified by these studies included NO<sub>2</sub>, CH<sub>2</sub>N, and (NO<sub>2</sub>)<sub>2</sub>. Thermal decomposition of RDX below its melting point was observed by means of EPR in experiments performed on neat RDX and on RDX in solution with TNT [354]. Kinetic information for the production and depletion of an RDX intermediate radical species and for

the production of  $\text{NO}_2$  was obtained for RDX/TNT mixtures over a temperature range from 398 to 458 K (125 to 185 °C). The activation energy for the production of the RDX intermediate radical was 233 kJ/mol (55.6 kcal/mol), while apparent activation energies for the decay of this species and for the production of  $\text{NO}_2$  were 200 and 125 kJ/mol (47.7 and 29.8 kcal/mol), respectively. The RDX intermediate radical was also observed in neat RDX from 448 to 478 K (175 to 205 °C).

Another intermediate in the decomposition of RDX is the nitronylnitroxyl free radical [355], but a critical review of these data suggested that these radicals are not primary decomposition products, but are formed by the reaction of the radical products of thermal decomposition with molecular oxygen [356].

$\text{CH}_2\text{N}$  and  $\text{CH}_2\text{NO}$  are two key free radicals which play a pivotal role in the combustion of RDX and HMX near the burning surface. The H atom and OH radical produced by their decomposition are the most important chain-carriers in the combustion of these cyclic nitramine systems. Both  $\text{CH}_2\text{N}$  and  $\text{CH}_2\text{NO}$  radicals can be formed directly from the fragmentation of methylene nitramine,  $[\text{CH}_2\text{NNO}_2]$ , the building block of RDX and HMX [357].

RDX is thought to decompose largely by homolytic N—N bond cleavage, among other possible initiation reactions. Density functional theory (DFT) calculations indicated that the resulting secondary aminyl ( $\text{R}_2\text{N}^\bullet$ ) radical can abstract an oxygen atom from  $\text{NO}_2$  or from a neighboring nitramine molecule, producing an aminoxyl ( $\text{R}_2\text{NO}^\bullet$ ) radical [358]. Persistent aminoxyl radicals have been detected in electron-spin resonance (ESR) experiments and are consistent with autocatalytic “red oils” reported in the experimental literature. When the O-atom donor is a nitramine, a nitrosamine is formed along with the aminoxyl radical. Reactions of aminoxyl radicals can lead readily to the “oxy-*s*-triazine” product (such as the *s*-triazine *N*-oxide) observed mass spectrometrically by Behrens and co-workers [325]. In addition to forming aminoxyl radicals, the initial aminyl radical can catalyze loss of HONO from RDX.

### Experimental Studies of RDX Decomposition Kinetics

When now looking at a literature summary of the state of the knowledge of RDX and HMX decomposition mechanisms and products compiled in 1985, it is surprising how little was then known about the mechanism and intermediates of RDX and HMX decomposition [359]. There was mostly speculation about the mechanisms, typically assuming breakage of the N— $\text{NO}_2$  bond as the initial reaction. A list of identified reaction products was given, but it was not known where they came from or how they were formed. It was suggested to use isotope labeling, but (with a few exceptions using  $^{15}\text{N}$ ) it had not yet been extensively done at that time.

The thermal decomposition of 1,3,5-trinitro-2-oxo-1,3,5-triazacyclohexane (keto-RDX) was investigated by 70 eV electron impact and chemical ionization mass spectra [360]. The mass spectra were similar to those of RDX. The laser-induced mass-spectra implied that the first step of keto-RDX decomposition is the elimination of  $\text{NO}_2$  or HONO and subsequent cleavage of the triazacyclohexane ring. The activation en-

ergy was determined by two methods: (1) by measuring the rate of NO evolution by chemiluminescence and (2) by DSC per ASTM E 698–79. No significant differences in bond-breaking energies for RDX and keto-RDX were found. See also [361, 362].

### Computational Studies of RDX Decomposition Kinetics

Pathways involving initial cleavage of an N–N bond account for only about one third of the gas phase product yield. A theoretical classical orbital dynamics study supported the viability of this depolymerization pathway [363]. A model potential energy surface was constructed to approximately reproduce known features of the RDX molecule. Dissociation was assumed to take place either by simple N–N bond rupture or concerted triple bond fission, both are principal primary dissociation channels previously identified by molecular infrared multiphoton dissociation by Zhao, Hints, and Lee [339]. Dissociation rate branching ratios and rotational, vibrational, and translational energy distributions of the products were then determined as a function of ensemble energy for a potential energy surface having barriers of 160 and 200 kJ/mol (38.3 and 47.8 kcal/mol) to symmetric ring dissociation and to N–N bond fission, respectively. Calculated branching ratios and product-energy distributions were found to be in reasonable agreement with experimental values. See also [364].

A description of gas-phase reaction mechanisms of nitramine propellants was based on three chemical submodels and validated by comparison of model predictions with experimental measurements using reaction flux and sensitivity analyses to guide the process [365]. The submodels, validated over the entire range of experimentally studied conditions, were assembled to represent the gas-phase nitramine combustion mechanism. As an example of this iterative procedure, numerical results were presented for the ignition behavior of RDX.

In the gas phase, RDX is a relatively stable molecule which releases a large amount of energy upon decomposition. Although gas-phase unimolecular decomposition experiments suggest at least two major pathways, there is no mechanistic understanding of the reactions involving RDX or other energetic molecules (such as HMX and TATB) used in rocket propellants [366]. For the unimolecular decomposition of RDX, three pathways were proposed: (1) concerted decomposition of the ring to form three  $\text{CH}_2\text{NNO}_2$  ( $M = 74$ ) molecules, and (2) homolytic cleavage of an N–N bond to form  $\text{NO}_2$  ( $M = 46$ ) plus a free radical of RDX that is missing one  $\text{NO}_2$  group ( $M = 176$ ), which subsequently decomposes to form various products. Experimental studies suggest that the concerted pathway is dominant while theoretical calculations have suggested that the homolytic pathway might require significantly less energy. A third pathway was proposed: (3) successive HONO elimination to form 3HONO ( $M = 47$ ) plus stable 1,3,5-triazine (TAZ) ( $M = 81$ ) with subsequent decomposition of HONO to HO ( $M = 17$ ) and NO ( $M = 30$ ) and at higher energies of TAZ into three HCN ( $M = 27$ ). All three pathways were examined using first principles quantum mechanics density functional theory, including the barriers for all low-lying products. It was found that a threshold exists

at  $\sim 167$  kJ/mol ( $\sim 40$  kcal/mol) for which HONO elimination leads to TAZ plus 3 HONO, while N—N homolytic cleavage leads to RDR plus  $\text{NO}_2$ , and the concerted pathway is not allowed. Above  $\sim 218$  kJ/mol ( $\sim 52$  kcal/mol) the TAZ of the HONO elimination pathway can decompose into 3 HCN, while the HONO can decompose into  $\text{HO} + \text{NO}$ . Above  $\sim 251$  kJ/mol ( $\sim 60$  kcal/mol), the concerted pathway opens to form  $\text{CH}_2\text{NNO}_2$ . At a threshold of  $\sim 272$  kJ/mol ( $\sim 65$  kcal/mol), the RDR of the N—N homolytic pathway can decompose into other products. These predictions are roughly consistent with previous experimental results and should be testable with new experiments. This should aid the development of a kinetic scheme to understand combustion and decomposition of solid-phase RDX and related energetic compounds (e.g., HMX). The decomposition scheme for RDX is similar to that for HMX presented later.

For a mathematical expression describing the chemical structure and reactant/product profiles of RDX flames, key reactions and species were selected by numerical solution of a system of equations describing one-dimensional flows of a viscous, heat-conducting, reacting gas at pressures of 0.5–90 atm [367]. The structure of various flame zones and the role of individual steps and species in the chemical process were investigated. The chosen kinetic mechanism consisted of 263 elementary steps and 43 species, mostly based on literature data of rate constants of elementary steps. A typical flame structure was calculated for RDX combustion under irradiation as in laser-assisted combustion. Various reaction paths in the RDX vapor decomposition zone had to be considered, including the effects of the mass flow rate and two-dimensional nature of the gas flow on the flame structure. Calculation results were then compared to experimental data and agreed moderately well with each other.

A traditional solid-state chemistry approach, applied to the essentially molecular problem of the energetic barrier for decomposition, gave qualitatively new results to the thermal decomposition of solid RDX, and new perspectives in the detonation initiation theory development in general [368]. Quantum-chemical simulations of the thermal decomposition of solid RDX by means of the Hartree–Fock method combined with the cluster and periodic models indicated that the dissociation of the RDX molecule in the bulk crystal is characterized by the different energetic barriers for cleavage of N— $\text{NO}_2$  bonds, unlike the gas-phase molecule, where all three of the energies are equal. It was also shown that a rupture of the N— $\text{NO}_2$  chemical bond requires less energy for an isolated molecule than for a molecule placed in the bulk of the solid. The situation changes if the molecule is close to the free surface of the crystal. In this case, less energy is required to break the bond than for a bulk molecule. Similar observations were made for HMX decomposition [43].

### Catalysts for Thermal Decomposition of RDX

The general theory is that catalysts that can accelerate the decomposition of nitramines will also accelerate their burning rate. RDX is often added to composite modified double-base propellants or composite AP-based propellants to boost their performance and reduce their signature. In those applications, the propellant may

contain burning rate catalysts that will affect not only the burning of NC or AP, but will also affect the burn rate of RDX. Other burning rate increasing catalysts have been evaluated specifically for RDX-based nitramine propellants.

Effective burning rate catalysts for nitramine propellants had not yet been found as of 1984 [324]. One of the catalysts evaluated for nitramine decomposition is potassium decaborate  $K_2B_{10}H_{10}$  or potassium dodecaborate  $K_2B_{12}H_{12}$  [359]. The thermal decomposition of HMX, RDX, and propellants, with and without catalysis by  $K_2B_{12}H_{12}$  or  $K_2B_{10}H_{10}$ , was examined by GC-MS, including the less-volatile decomposition products [369]. Pyrolysis-GC-MS on HMX-GAP and HMX-PEG compositions with and without  $K_2B_{10}H_{10}$  showed that one of the products identified was probably 1,3,5-triazine. This was believed to be formed from HMX via 1,3,5,7-tetraazacyclooctatetraene; this is consistent with the known thermal decomposition behavior of cyclooctatetraene and its aza derivatives. 1,3,5-triazine formation by trimerization of HCN is believed to be relatively unimportant. There was also an unknown component whose highest mass peak was at  $m/e$  70, but formation of the  $m/e$  70 unknown decreased with increasing temperature. The decomposition and combustion of HMX and RDX, and of propellants derived from them, by salts containing boranate anions with alkali metal anions leads to propellants with higher burning rates. The pure salts appeared to be stable under vacuum or inert gas to about 973–1073 K (700–800 °C), but there was a report of  $H_2$  evolution at lower temperatures (ca. 573–873 K = 300–600 °C, depending on the nature of the salt) [370]. When the salts were heated together with RDX, considerable enhancement of the decomposition rate of RDX was observed. This began at the melting temperature of pure RDX and became intense, leading to a lower, much sharper decomposition exotherm. These observations seem consistent with a catalysis mechanism involving attack of the B–H hydrogens of the catalyst on the nitramine.

Perovskite-type  $LaMnO_3$  and  $La_{0.8}Sr_{0.2}MnO_3$  oxides with high specific surface areas have already been tested as catalysts for other applications, such as the catalytic decomposition of HAN- or HTP-based monopropellants. Now they have also been evaluated as catalysts for RDX thermal decomposition and characterized by XRD, FT-IR, SEM, and XPS [371]. The catalytic activities of perovskites on thermal decomposition of RDX were investigated by TGA-DSC techniques. The catalytic activity of  $La_{0.8}Sr_{0.2}MnO_3$  was higher than that of  $LaMnO_3$  for thermal decomposition of liquid RDX.

The addition of some coated aluminum nanopowders lowered the onset temperatures of RDX, TNT, and glycidyl azide polymer decomposition by ~20 °C [372]. Outgassing results obtained for various RDX/aluminum mixtures at 373 K (100 °C) showed that uncoated 120-nm Al enhanced the low-temperature solid-phase decomposition of RDX.

### 12.2.3.3 Radiolysis of RDX

Irradiation of RDX and HMX at the  $1.2 \times 10^6$  roentgen dose level caused no measurable nitramine decomposition [373].

#### 12.2.4 Strand Burning of RDX

RDX is never used as a rocket propellant by itself, only as an ingredient in composite-modified double-base propellants and in nitramine propellants. Thus studies of strand burning of RDX by itself, as summarized in this section, would be strictly of academic interest. In addition to linear strand burning studies of RDX pellets in constant pressure bombs, sometimes also the mass burning rates were derived from pressure curves in constant volume bombs ("ballistic bombs").

There are hundreds of publications on burning rates of solid propellants containing RDX, but a few less on burning rates of RDX by itself. As with any explosive, there is always the hazard that a well-behaved combustion of RDX may unexpectedly transition to a detonation.

The deceleration of chemical reactions in the deflagration of energetic materials by addition of inert ingredients was studied in a constant pressure bomb over the pressure range from 1 to 1000 atm [374]. It was shown that addition to RDX of deoxidants (10%) such as derivatives of urea, diphenylamine, or *o*-aminophenol decreased mass burning rates ( $R_m$ ) by a factor of two to three. Efficiency of the additives was greatest at low pressures and decreased with increasing pressure. One of the most effective additives, urethane, decelerated also the  $R_m$  of TNT, PETN, picric acid, nitroglycol, and DINA.

The deuterium isotope effect which identifies rate-controlling reaction steps in high energy processes was measured in combustion experiments with HMX/HMX-d8 and RDX/RDX-d6 [375]. The deuterium isotope effect directly identified the covalent chemical bond rupture which controls the energy release rate in the condensed phase reactions associated with decomposition and combustion processes. Although a complex myriad of chemical reactions occur during these events, the deuterium isotope effect operates throughout the actual process itself and is specific to the rate-determining bond rupture which controls the energy release rate of pure liquid and solid energetic compounds. HMX/HMX-d8 decomposition studies revealed that the thermochemical rate-controlling step is dependent upon physical state. Solid-state HMX decomposition is controlled by C—H bond rupture; its mixed-melt phase is regulated by the strength of attractive thermophysical crystal lattice interactions, and the liquid state is again chemically controlled, but in this case, by ring C—N bond cleavage. The deuterium isotope effect technique has been extended into the combustion regime using HMX and HMX-d8 and it was found that its global burn rate is kinetically controlled by condensed phase covalent C—H bond rupture.

Assuming a consistent mechanism between decomposition and combustion, the observed isotope effects suggested that a carbon–hydrogen bond rupture in HMX and RDX is the rate-controlling process in the combustion of nitramine propellants [376].

The condensed-phase kinetic deuterium isotope effect (KDIE) approach that determines the rate-controlling steps in a slow decomposition process can be extended into the progressively more drastic high energy regimes encountered with rapid pyrolytic decomposition/deflagration, plus the higher temperature/

higher pressure combustion, thermal explosion, and detonation events [377]. The KDIE can determine mechanistic relationships between the slow thermochemical decomposition process and more energetic events.

High pressure (3.55 and 6.89 MPa = 500 and 1000 psig) burn rate comparisons from the combustion of solid RDX and perdeuterium-labeled RDX-d6 cylindrical pressed pellets revealed a large kinetic deuterium isotope effect (KDIE) [378]. This experimental KDIE confirmed that chemical reaction kinetics are a significant mechanistic factor in controlling the inherent RDX burn rate and further showed the heterocyclic six-membered ring RDX rate-controlling mechanistic step during combustion is the same as that previously reported for its larger eight-membered ring HMX homologue.

A laser-stimulated recoil force technique can be used to perturb the steady combustion of an energetic material and the dynamic burning rate can be obtained from the recoil measured by a sensitive piezoelectric load cell. By tuning the frequency of the modulated laser radiation, the response of the burning surface can be measured and an eventual resonance frequency determined that indicates the propensity of this propellant to suffer failures from combustion instabilities. A “whistling Pete” may be acceptable for entertainment fireworks, but it is not a desirable property of a rocket propellant. Laser-stimulated recoil force measurements have been applied to burning RDX or HMX and many propellant ingredients and formulated propellants [379–382].

A CW CO<sub>2</sub> laser at heat fluxes of 100 and 300 W/cm<sup>2</sup> was used to assist the decomposition and combustion of RDX and HMX, while using a triple quadrupole mass spectrometer and a thermocouple to perform species and temperature profiles measurements in the gas phase [383]. The major species at the surface were H<sub>2</sub>O, H<sub>2</sub>CO, HCN, NO<sub>2</sub>, N<sub>2</sub>O, N<sub>2</sub>, CO, and NO at atmospheric pressure with both heat fluxes. There was no CO<sub>2</sub> existing at the surface. The mol fraction of triazine was found to be approximately 2.5% at the surface, which had not been reported by previous investigators during combustion of RDX. These data were particularly helpful for comparing the products of pyrolysis to those from laser-assisted combustion. The temperature profiles in the gas phase and species concentrations obtained at the surface with heat fluxes of 100 and 300 W/cm<sup>2</sup> were used as inputs to a one-dimensional gas-phase flame model, but disagreement between the model and experiments for stable species was substantial. Hot surface or filament heating methods offer the advantage of fast pyrolysis with independent control over the heating rate and final temperature. The disadvantage of hot surface or hot filament heating is that the heating rates are lower than those that are possible with the CO<sub>2</sub> laser.

HMX burning laser and pressure-driven response experiments were conducted at 1, 2, and 3 atm in argon [384]. Under these conditions a mean laser flux was necessary to sustain combustion. In addition, microthermocouple measurements were performed to obtain information required to interpret the results and to estimate condensed phase heat release. Modeling of the gas-phase region was used to estimate the heat feedback from the flame to the surface. Due to the presence of the laser heat flux, the flame was significantly “stretched” resulting in heat feedback to the surface that

was substantially less than that without the laser flux. As a result of the lower heat feedback to the sample surface, the steady and unsteady laser fluxes dominated over the steady and unsteady heat feedback in the laser-driven testing, so the laser flux was not simply a perturbation on the steady heat feedback. Laser-driven response experiments on HNIW showed that the response amplitude decreased with an increase in pressure. The unsteady component of the laser flux induced an unsteady component of the gas-phase heat feedback that was out of phase with the laser flux. The laser-driven experiments measured the response of the propellant to this net unsteady flux that was incident on the propellant surface. The increase in pressure increased the unsteady gas phase heat feedback and hence decreased the net unsteady flux on the propellant surface and resulted in the lower response amplitudes.

Small perturbations of burning nitramines near the stability limit give rise to undamped oscillations of the burning rate. Measurements of strand burning rates of RDX and HMX in the range of 1–4 atm, with and without modulated laser augmenting irradiation, showed that at atmospheric pressure in addition to the usually recorded flame combustion regime, RDX has a regime of flameless gasification under irradiation [385]. Both of the regimes were followed by high-frequency oscillations exceeding 600 Hz. The source of these oscillations was assumed to be the boiling and rupture of bubbles at the surface.

The strand burning rates of RDX were compared to those of ADN, HNF, HMX, CL20, and AP [386]. RDX powder was pressed into rectangular pellets using 20  $\mu$ L of acetone per 0.5 g pellet as a processing aid. The pellets were pressed at 621 MPa and held at that pressure for 5 min. The density of the resulting pellets was 95.5–99.1% of the theoretical maximum density. Figure 19 is a comparison of NAWCWD data with literature data. The data points match very closely.

Figure 20 is a graphical representation of the pressure and temperature sensitivity of burning rates of pressed pellets of RDX. The short section for 423 K initial temperature is the result of only two pressure data points available at 0.69 and 1.38 MPa.

In extending conventional burning rate and pressure exponent measurements, additional data were used to determine the temperature sensitivity coefficient  $\sigma_p$  of the burning rate of RDX, HMX, HNIW, and three oxidizers [387]. The simplest means of determining a value of  $\sigma_p$  is to measure the burning rate of a particular material as a function of initial temperature, take the natural logarithm of the burning rate values, and determine the burning rate temperature sensitivity as the slope of the line through a plot of the natural logarithm of the burning rate vs. the initial temperature. The main requirement is to obtain a consistent and reliable set of burning rate data at various initial temperatures and pressures. Figure 21 gives a comparison of the temperature sensitivity coefficients of three nitramines. In the case of RDX, the temperature sensitivity goes through a minimum over a wide pressure range. The temperature sensitivities of the burning rates of HMX and HNIW are much higher than that of RDX.

Absorption spectroscopy has been applied to low-pressure, self-deflagrating RDX flames in an attempt to develop detailed chemistry combustion models [388, 389].

Semi-empirically determined production rates of reactants from the solid propellant surface together with a detailed gas-phase elementary reaction set were used to develop a kinetic model. The spatial profiles of two low-concentration, highly reactive, short-lived diatomic species, CN and NH, were obtained at pressures varying from 1 to 2 atm in air. Two major species, NO and OH, were also profiled using this technique. As the pressure was increased, the CN and NH concentrations peaked closer to the combusting surface over a smaller spatial extent. Measurements of the concentration of NO species showed a peak concentration of 25 mol-% occurring at a position of 0.12 mm above the surface of the propellant. In the final flame region, measured OH concentrations of 1.7 mol-% agreed well with adiabatic reaction calculations performed with the NASA Lewis thermochemical equilibrium code. The model peak positions and relative concentrations of NO, OH, CN, and NH were in good agreement with experiments. During the course of these spectroscopic measurements, burning rates for RDX over a pressure range of 1 to 2 atm were determined. These values ranged from 0.23 mm/s at atmospheric pressure to 0.50 mm/s for 2 atm and were noticeably lower than some of the other published measurements. Calculations based on the proposed model predicted a burning rate of 0.29 and 0.54 mm/s for the same pressure levels.

#### 12.2.4.1 Modeling of Strand Burning of RDX

The importance of a molten foam layer on the surface of a burning RDX propellant has been acknowledged, but models capable of predicting the concentration and temperature profiles across the flame zone were difficult to develop because of the complexity involved. A theoretical model which described the detailed reaction-zone structure of RDX pellets burning under constant ambient pressure was developed which considered a time-dependent, deflagrating RDX propellant which consisted of three different zones: (1) solid-phase conductive heating zone, (2) liquid/gas bubble two-phase reaction foam zone, and (3) gaseous chemically reacting flame zone [390]. The model included 38 chemical species and 158 chemical reactions. Major parameters that could be printed out with the output of this model included burning rate, foam layer temperature and species profiles, bubble dynamics (e.g., bubble growth and bubble velocity), and void fraction of the foam zone.

A similar model for self-sustained combustion of RDX pellets takes into account detailed chemical kinetics and transport phenomena in the gas phase, and thermal decomposition and subsequent reactions in the condensed phase [391]. The formation of gas bubbles in the subsurface layer due to molecular degradation and evaporation was also included to provide a complete realistic simulation. Various important aspects of RDX burning characteristics were systematically examined over a broad range of pressure, with special attention given to the effect of the subsurface two-phase flow on propellant deflagration. Good agreement between calculated and measured burning rates as well as their pressure and temperature sensitivities was achieved. Profiles of species concentrations revealed a multistage reaction mechanism in the gas phase. The temperature profile, however, exhibited a monotonic increase from the surface to the final flame zone. No evidence could be obtained for the existence of a temperature plateau in the dark zone, consistent with some earlier experimental observations of such a plateau.

Laboratory experiments as well as theoretical computations have contributed to a better understanding of the thermal decomposition and linear burning rates of nitramines; however, because of the lack of thorough experimental and theoretical data on the chemical structure of a combustion wave, the kinetics of the process in the narrow zone adjacent to the burning surface had not been adequately studied. A systematic review of literature data on the thermal decomposition was trying to summarize what was known and point in the direction where additional work was needed [367, 392–394].

A one-dimensional, steady-state numerical model of the combustion of homogeneous solid propellants like RDX or HMX was modeled in three regions: solid, two-phase (liquid and gas) and gas [395]. Conservation of energy and mass equations were solved in the two-phase and gas regions and the eigenvalue of the system (the mass burning rate) was converged by matching the heat flux at the interface of these two regions. The chemical reactions of the system were modeled using a global kinetic mechanism in the two-phase region and an elementary kinetic mechanism in the gas

region. There was reasonable agreement between experimental data for RDX, HMX, and GAP and model predictions for burning rate, temperature sensitivity, surface temperature, adiabatic flame temperature, species concentration profiles, and melt-layer thickness. The combustion characteristics of RDX and HMX are similar because of their similar chemistry. Differences in combustion characteristics arose due to differences in melting temperature, vapor pressure, and initial decomposition steps.

To develop a comprehensive model of nitramine propellant ignition and combustion, a numerical analysis was developed to solve both transient and steady-state combustion, including detailed finite rate chemical kinetics, thermodynamic phase transition, and subsurface reactions [396]. The model was then expanded to predict ignition phenomena. Modeling work was complemented by conducting fast thermolysis experiments with RDX, CAB, NC, and mixtures of RDX and binders. Intrusive mass spectroscopic techniques were utilized to acquire gas phase species profiles under conditions of laser-assisted burning of monopropellants and composite propellants. Nonintrusive diagnostic techniques were developed and used to determine temperature and species profiles within propellant flames at elevated pressures, which were needed for model validation.

RDX and HMX have similar structures and strand burning rates. However, the burning-rate temperature sensitivity  $\sigma_p$  is significantly different between RDX and HMX at low pressure. Efforts to mathematically model the steady-state burning of RDX and HMX with detailed chemical kinetics in the gas and decomposition in the condensed phase have succeeded in modeling burning rates at a specific initial temperature. However, all have underpredicted the  $\sigma_p$  trends of HMX at low pressure and have not differentiated between the  $\sigma_p$  values of RDX and HMX. RDX and HMX both burn with a thin multiphase surface of bubbles in the liquid melt layer. A liquid–bubble model was developed to improve  $\sigma_p$  predictions [397]. In order to predict the experimentally observed  $\sigma_p$  values with the model, first, evaporation in the subsurface was limited to near the gas–liquid interface. Second, the difference in surface temperature at different initial temperatures was adjusted to follow trends in experimental data. Third, the effect was added to the calculation of the bubble velocities. For RDX, there was little change in the calculated  $\sigma_p$  value with the addition of the liquid–bubble submodel.

#### 12.2.4.2 Flame Structure and Temperature Profiles of RDX Flames

The chemical flame structure of RDX or HMX burning in an air or argon atmosphere was investigated at a pressure of 0.1 MPa using molecular beam mass spectrometry [398, 399]. Eleven species ( $H_2$ ,  $H_2O$ , HCN,  $CO_2$ , CO,  $N_2$ ,  $N_2O$ ,  $CH_2O$ , NO,  $NO_2$ , and nitramine vapor [HMX or RDX]) were found in flames of RDX and HMX during self-sustained combustion. It was found that nitramine flames at a pressure of 0.1 MPa have a two-zone structure: In the first flame zone, the consumption of nitramine vapor (HMX or RDX),  $NO_2$ ,  $CH_2O$ , and partial consumption of  $N_2O$  with formation of  $H_2$ ,  $H_2O$ , CO,  $N_2$ ,  $CO_2$ , HCN, and NO occurs. In the first, narrow, zone

0.15 mm wide adjacent to the burning surface, decomposition of RDX vapor and the reaction of  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ , and  $\text{CH}_2\text{O}$  with the formation of HCN and NO occur. In the second zone, 0.85 mm wide, HCN is oxidized by NO to form the final combustion products. Using experimental data, gross-reactions for the gasification of nitramines at atmospheric pressure were determined:

The same method was also applied to formulated propellants of RDX or HMX with GAP as the binder [400].

Experimental investigations of the burning wave structures of HMX and RDX were carried out by microthermocouple measurements at 1–70 atm [401]. Data on burning-surface temperature, heat release in solid, heat feedback from gas to solid, and heat-release rate in gas near the surface were obtained by this method. The data showed that in the condensed phase of combustion waves of nitramines, evaporation and thermal decomposition occur simultaneously, with heat release in the solid being negative at  $P < 5 - 10$  atm and positive at  $P > 5 - 10$  atm. Activation energies of HMX and RDX decomposition in combustion waves were derived from the burning rate dependence on initial sample temperature.

Temperature profiles of self-deflagrating RDX in a nitrogen environment at pressures up to 0.79 MPa were determined using UV/Visible absorption spectroscopy and fine-wire thermocouples [402]. The burning surface of RDX was covered by a very dynamic two-phase foam zone, and the thickness of the foam zone decreased very rapidly with an increase of pressure. The temperatures within the foam zone were readily identified in the thermocouple traces, especially at low pressures. Depending on the pressure, the temperature was found to be around 500–520 K at the bottom surface of the foam zone, and around 590–690 K at the top surface of the foam zone. These temperatures were higher than the RDX melting temperature (477 K at 1 atm). A relationship between RDX burning surface temperature and pressure was developed for pressures between 1 and 90 atm using data from this study and Zenin's data [401]. The final flame temperature of RDX increases with an increase of pressure: 2950 K at 0.17 MPa, 3002 K at 0.45 MPa, and 3204 K at 0.79 MPa, which agreed well with chemical equilibrium calculations. See also [365].

#### 12.2.4.3 Unsteady, Oscillatory Burning of RDX Flames

Combustion of RDX under self-deflagrating and  $\text{CO}_2$  laser-assisted conditions at atmospheric pressure in air was studied measuring near-surface temperature (embedded microthermocouple), melt layer thickness, and sensitivity of burning rate to initial temperature and radiant flux [403]. Unsteady burning measurements of oscillatory burning behavior were obtained using the laser-recoil technique. Thermocouple data showed a relatively thick (several hundred  $\mu\text{m}$ ) melt layer, which increased in thick-

ness with increasing laser flux, but remained at a relatively constant temperature of about 650 K. The fluctuating, spatially isothermal (time-averaged) nature of the melt layer suggested that a bubbling/mixing mechanism plays an important transport role in this zone. The temperature- and radiant flux-burning rate sensitivity data showed that the equivalence principle is reasonably accurate for RDX under these conditions.

One means to achieve the increased rocket propellant performance needs of the future is to increase solid rocket motor operating pressures. Increased operating pressures can be achieved with the improved rocket motor case technology that is currently available. While attractive, this mode of performance increase is not without its own practical limitations. Solid rocket propellants often experience an increase in burning rate pressure exponent at elevated pressures. A burning rate pressure exponent near unity may result in a motor explosion. Combustion instability is also an additional problem at elevated pressures. High pressure oscillations were observed in some of the closed bomb firings made with RDX and appear to be related to a delayed ignition. Burning rate measurements were measured for nitramines over the pressure range of 0.69 to 138 MPa [404]. A combination of high pressure window bomb and closed bomb combustion tests was used to obtain the combustion data.

### 12.2.5 Toxicity of RDX

The TLV TWA for RDX vapor inhalation in air is  $1.5 \text{ mg/m}^3$  (NIOSH). An IDLH value has not been established.

In a study of mammalian toxicity of RDX, acute oral LD<sub>50</sub> values were  $119.0 \pm 4.6$ ,  $118.7 \pm 4.5$ , and  $118.1 \pm 2.8 \text{ mg/kg}$  in male, female, and combined sexes of rats [405]. The corresponding mouse LD<sub>50</sub>s were  $97.2 \pm 8.7$ ,  $58.9 \pm 26.8$ , and  $80.3 \pm 9.6 \text{ mg/kg}$ , respectively. There were no statistically significant sex difference in either species. Toxic signs, including gasping, labored breathing and convulsions, indicated neurotoxicity. In the 90-day rat subchronic toxicity study,  $40 \text{ mg kg}^{-1} \text{ day}^{-1}$  was toxic, while the next lower dose ( $28 \text{ mg kg}^{-1} \text{ day}^{-1}$ ) was not. The only consistent toxic effect observed was decreased weight gain. Mice were less affected in the 90-day subchronic study, since a dose of  $320 \text{ mg kg}^{-1} \text{ day}^{-1}$  was required to produce definite toxicity. Effects seen included hyperactivity, unscheduled deaths, increased liver and kidney weight accompanied by hepatocellular vacuolization or microgranulomas and tubular nephrosis. RDX was not mutagenic in the Ames Salmonella/microsome test at doses up to  $1 \text{ mg/plate}$  and in the rat dominant lethal mutation test at doses up to  $50 \text{ mg kg}^{-1} \text{ day}^{-1}$ . RDX was not teratogenic to rats or to rabbits at doses up to  $20 \text{ mg kg}^{-1} \text{ day}^{-1}$  but that dose produced severe nonteratogenic toxicity. The two-generation reproduction study produced severe toxicity (particularly neurotoxic effects and unscheduled deaths) but no specifically reproductive toxicity at diets giving a nominal  $50 \text{ mg kg}^{-1} \text{ day}^{-1}$ .

#### 12.2.5.1 Environmental Effects of RDX

Contamination from unexploded munitions and explosive residues from partial explosions may persist in the environment for a long time. RDX or HMX from unex-

ploded ammunitions may soak into soil, where some of it is consumed by biodegradation [406]. The main concern from an environmental point of view is the waste water from RDX/HMX manufacturing plants which may still contain unreacted intermediates and spent acid. The solubility of RDX in water is relatively low, so that only little RDX product is in the filtrate after the product has crystallized. In comparison to those concerns, problems arising from the use of RDX or HMX in CMDB/nitramine rocket propellants are only minor. Because only limited resources were available when preparing this book, complete coverage of the environmental effects of RDX and/or HMX could not be included in this chapter of the book.

### **12.2.6 Handling of RDX**

One method to destroy RDX in contaminated waste water is by reduction in alkaline solution (dispersion) with aluminum powder, accelerated by ultrasound sonication [407]. Another method for treatment of RDX-contaminated waste water includes bioremediation in open ponds.

### **12.2.7 Explosive and Fire Hazards of RDX**

#### **12.2.7.1 Drop Weight Impact Sensitivity of RDX**

The drop weight impact sensitivity of RDX in the BAM test apparatus is 7.5 N m. Impact sensitivity of a 20-mg sample in the Bureau of Mines apparatus is 0.3 m with a 2-kg weight. Impact sensitivity of an 18-mg sample in the Picatinny apparatus is 0.2 m with a 2-kg weight.

Strain-gauge measurements on RDX and other explosives showed that the pressures attained during drop-weight impact are typically 0.5–1 GPa (5–10 kbar) and the duration of impact 300–500  $\mu$ s [408].

A dislocation pile-up avalanche model was used in an effort to explain the crystal size dependence for hot spot-controlled initiation of chemical decomposition in RDX crystals subjected to drop-weight impact testing [409]. Deformation-induced temperature rises, hot spot sizes and lifetimes are related to previously reported values for direct thermal decomposition and a chemical reaction heat generation rate was estimated from available kinetic data.

Looking into what creates hot spots and makes RDX crystals ignite during crushing impact, elastic, plastic, and cracking indentation measurements obtained in nano- to micro- to macroindentation hardness tests of RDX crystals were described on a hardness stress-strain basis and assessed in terms of a dislocation pileup avalanche mechanism for hot-spot generation associated with sudden crack formation [410, 411]. The model attempted to interpret particle size influence on the drop-weight height for 50% probability of onset of reaction and was extended to include results for  $\epsilon$ -HNIW crystals.

An interlaboratory comparison of seven lots of commercially available RDX was conducted to determine what properties of the nitramine particles can be used to as-

sess whether the RDX has relatively high or relatively low sensitivity [412]. The materials chosen for the study were selected to give a range of HMX content, manufacturing process and reported shock sensitivity. Impact sensitivity is not a good predictor of shock sensitivity for these types of RDX. Although most RDX has low HMX content, that characteristic alone is not sufficient to guarantee low sensitivity. A range of additional analytical chemistry tests (HPLC and DSC) were conducted on the material to see how they relate to sensitivity.

Reduced sensitivity RDX (RS-RDX) depends on both crystal structure and chemical composition (contaminant content). There are publications on work done to determine which property or properties may explain the less sensitive behavior of formulations with RS-RDX. There is no dedicated specification to apply to RS-RDX. Standard RDX produced by the Bachmann process (when re-crystallized under I-RDX conditions in order to obtain RS-RDX) does not retain its low sensitivity after aging. It has been shown that the higher sensitivity of RDX produced by the Bachmann process, or the evolution of sensitivity after aging of RS-RDX produced from Bachmann RDX, may be linked to the presence of HMX during crystallization. There are indications that removal of HMX from Bachmann RDX may lead to RS-RDX, which retains its RS character even after aging [413].

There is a relationship between the weakest N—N bonds in a cyclic nitramine molecule and its impact sensitivity [414]. The relationships found between the bond dissociation energy values and logarithms of impact sensitivity of these nitramines, expressed as drop energy, were not unambiguous.

The surface and thermal properties of seven different varieties of crystalline RDX from five different manufacturers were studied using DSC and atomic force microscopy (AFM) [415]. The specific varieties of the RDX studied were chosen because intensive characterization of the materials already existed including shock sensitivity and HMX impurity levels. AFM scans revealed a variety of surface defects. To quantify the surface defects on the crystalline surface of the RDX particles, surface roughness measurements were performed to correlate the observed surface, HMX impurity levels and DSC thermal curve properties with the known shock sensitivities of the material. It was found that a statistically significant relationship existed between surface roughness and the shock sensitivity of the material, while no relationship was observed between the DSC thermal properties and either surface roughness or shock sensitivity. The HMX content greatly affected the thermal properties of RDX but was not correlated with the shock sensitivity.

The shock sensitivity of RDX is dependent upon many factors including crystal size, morphology, internal defects, surface defects, and HMX content. With the arrival of reduced sensitivity RDX (RS-RDX) and the drive towards insensitive munitions, understanding what influences sensitivity has become a significant topic within energetic materials research. The parameters which influence sensitivity were investigated in a round robin analysis exercise. However, large discrepancies were seen between different laboratories involved in a round robin, so the results were inconclusive. It be-

came necessary to clarify how crystal properties and the manufacturing process affect RDX sensitivity [416]. Optical microscopy showed that internal defect content varied widely and was affected by the manufacturing process. A good correlation between sensitivity and defect quantity was seen for RDX lots produced by the same method. Microscopic examination showed a wide range of morphology variations, which was influenced by the method of production. Scanning electron microscopy also showed that surface defects were approximately correlated to shock sensitivity. However, general surface roughness agreed better with sensitivity than the number of specific defects such as cracks and holes. The mechanical properties of the RDX samples were investigated using nanoindentation. This showed a good correlation between the quantity of internal defects and modulus of elasticity, hardness, and creep. There was also a good agreement between these parameters and sensitivity. DSC results indicated that crystal size influenced the decomposition rate. The melting endotherm onset temperature and energy was correlated with HMX content.

Trapped gas bubbles may contribute to impact sensitivity of explosives. In order to eliminate contributions by adiabatically compressed gas bubbles as hot spots, some drop weight impact sensitivity tests have been conducted in a vacuum.

#### **12.2.7.2 Friction Sensitivity of RDX**

The friction sensitivity in the BAM friction test apparatus is 120 N pistil load.

#### **12.2.7.3 Explosive Shock Sensitivity of RDX**

The published literature on shock sensitivity of granular explosives like RDX or HMX presents a somewhat confusing picture. A particular problem is that the results of different studies often cannot be directly compared due to the different experimental methods and purity of the samples used to determine sensitivity. Some experimenters do not state which crystal polymorph modification of HMX was being tested.

In order to identify the most important crystal features that cause hot spots to develop in a granular explosive, various batches of gently consolidated, tapped granular RDX having a wide range of crystal shapes, void contents, and surface qualities were tested for their shock sensitivity. The range of possible factors included internal void content, particle size, HMX content, and the number and size of internal defects.

#### **12.2.7.4 Explosive Performance of RDX Detonation Velocity of RDX**

The detonation velocity of confined RDX is 8750 m/s at  $\rho = 1.76 \text{ g/cm}^3$ . When searching for a relationship between bond dissociation energies of the weakest bond in the molecule and the detonation velocity, no unambiguous relationships could be found between the logarithms of detonation velocities and bond dissociation energies of cyclic nitramines [417]. The reason of this lack of correlation mainly lies in real conformations of these molecules and intermolecular force effects in real crystals.

### Critical Diameter of RDX Detonations

A theoretical analysis of the effect of RDX particle size on critical diameter showed that the size of RDX particles has an effect on critical diameter: the smaller the particle size, the smaller the critical diameter of the charge [418, 419].

### Lead Block Indentation of RDX

The lead block bulging of the cavity caused by RDX detonation is  $415 \text{ cm}^3/10 \text{ g}$ . Other sources give the lead block indentation of RDX as  $480 \text{ cm}^3/10 \text{ g}$ . The Trauzl lead block indentation of RDX is 157% of that of TNT.

### Ballistic Mortar Performance of RDX

The ballistic mortar performance of RDX was calculated by a simplified method and compared to experimental measurements. The ballistic mortar performance of RDX was predicted to be 152% of that of TNT and measured as 150% of that of TNT [88].

#### 12.2.8 Intermediates in the RDX and HMX Synthesis

The cyclic nitramine 3,7-dinitro-1,3,5,7-tetraaza-bicyclo[3,3,1]nonane,  $\text{C}_5\text{H}_{10}\text{N}_6\text{O}_4$ , also called dinitropentamethylenetetramine (DPT), is an intermediate in the synthesis of HMX and RDX, and has an impact sensitivity lower than that of HMX or RDX. The DPT molecule has both the eight-membered C—N ring of HMX and the six-membered C—N ring of the RDX molecule. The crystal structure of DPT was determined by XRD for comparison with those of both HMX and RDX [420]. The crystals are monoclinic, space group  $P2_1/c$ , with  $a = 9.345(5) \text{ \AA}$ ,  $b = 8.284(5) \text{ \AA}$ ,  $c = 11.566(5) \text{ \AA}$ ,  $\beta = 103.6^\circ$ , and  $Z = 4$ . The XRD density of DPT is  $1.682 \text{ g/cm}^3$ .

### 12.3 RDX Derivatives

Substituting some or all of the hydrogens in the hexahydrotriazine ring which forms the skeleton of RDX with more energetic groups will result in energetic materials that have improved properties. Another variation is the replacement of one or more nitramine groups in RDX with other energetic linkages.

One of the derivatives where three of the hydrogens have been replaced with trifluoromethyl groups, is 1,3,5-trinitro-2,4,6-tris(trifluoromethyl)-hexahydrotriazine (TTFMRDX). Even more energetic compounds can be obtained if the hydrogens are replaced by difluoroamino groups instead of trifluoromethyl groups, which can be synthesized by way of 1,3-diazacyclohexane precursors [421].

### 13 Seven-Membered Ring Heterocyclic Nitramines

1,3,5-Trinitro-1,3,5-triazacycloheptane; 1*H*-1,3,5-triazepine, hexahydro-1,3,5-trinitro-; hexahydro-1,3,5-trinitro-1*H*-1,3,5-triazepine,  $M = 236.14$  g/mol,  $C_4H_8N_6O_6$ , TNCHP, HOMO, CAS RN [5790-78-3], with a m.p. of 438 K (165 °C) (decomposition), a homologue of RDX, was obtained in 38% yield by the nitrolysis with 99%  $HNO_3$  at 275–277 K (2–4 °C) of finely powdered methylenebis(3,6-dinitro-1,3,6-triazacycloheptane), m.p. 478 K (205 °C) (decomposition) which was obtained in 94% yield by heating  $(CH_2NHNO_2)_2$  in 37% formalin to 333 K (60 °C), cooling the product to 293 K (20 °C), and adding 28%  $NH_3$  [228]. See also [422]. According to other information, 1,3,5-trinitro-1,3,5-triazacycloheptane melts at 440–441 K (167–168 °C) and in the DTA the temperature at the maximum of the exotherm peak is 554 K (281 °C) [94]. 1,3,5-Trinitro-1,3,5-triazacycloheptane has no practical importance, it is mostly used in comparative studies with RDX to see what effect the widening of the ring structure might have on thermal stability of this molecule. It will also be examined in comparison to HMX to see what effect the tightening of the ring has on the stability of this molecule. Working in the other direction, studies have been extended beyond HMX to nitramine rings with five or even six  $-CH_2-N(NO_2)-$  linkages.

*N*-Nitroazacycloheptane has only one nitramine group instead of three in the molecule. *N*-Nitroazacycloheptane boils at 358–360 K (85–87 °C) at 267 Pa (2.0 mm Hg) and its index of refraction is  $n_D^{26} = 1.5045$ .

### 14 Eight-Membered Ring Heterocyclic Nitramines

1,3,3,5,7,7-Hexanitro-1,5-diazacyclooctane (HCO) has been evaluated as an alternate to HMX. The gross formula for HCO is  $C_6H_8N_8O_{12}$  with a molecular mass of 384.2 g/mol and a total oxygen content of 50% and an oxygen balance of –16.7% which is better than that of HMX or RDX (–21.6%).

HCO was synthesized in small samples, and the density was  $\rho = 1.875 \text{ g/cm}^3$ , the enthalpy of formation was  $\Delta H_f = -27.3 \text{ kJ/mol} = -6.52 \text{ kcal/mol}$  and the melting point was 523 K (250 °C) with decomposition [218]. The intermediates in the six-step synthesis procedure of HCO were too sensitive to make a scale-up of its production feasible.

## 15 Eight-Membered Ring Heterocyclic Nitramines with Four Nitrogen Atoms in the Ring

### 15.1 1,3,5,7-Tetranitro-1,3,5,7-tetraazacyclooctane, Octogen (HMX)

Cyclotetramethylenetetranitramine, also known as  $\text{C}_4\text{H}_8\text{N}_8\text{O}_8$ , octogen, HMX, 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane, octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine, 1,3,5,7-tetranitro-1,3,5,7-tetrazocane, CAS RN [2691-41-0],  $M = 296.155 \text{ g/mol}$ , is one of the most powerful and thermally very stable explosives. It is used as a rocket propellant ingredient in nitramine propellants, sometimes in combination with RDX, but not as widely as RDX because it is more expensive to manufacture. Since its preparation is significantly more difficult than that of RDX, it is not as widely used as its lower nitramine homologue.

1,3,5,7-Tetranitro-1,3,5,7-tetraazacyclooctane (HMX)

The name HMX comes from **H**igh **M**elting **eX**plosive and not from “Her Majesty’s Explosive,” as some people have suggested.

#### 15.1.1 Preparation, Production, and Availability of HMX

HMX is often formed as a by-product during the manufacture of RDX by the Bachmann process (prepared from hexamethylenetetramine, ammonium nitrate, nitric acid, and acetic anhydride). It is obtained as the sole product when 1,5-methylene-3,7-dinitro-1,3,5,7-tetraazacyclooctane is treated with acetic anhydride, ammonium nitrate, and nitric acid. This intermediate precursor can be made by reaction of acetic anhydride

with hexamethylenetetramine dinitrate. HMX produced by the Bachmann process may contain some RDX as a contaminant.

## 15.2 Physical Properties of HMX

The physical properties of HMX are summarized in Table 27. In the literature, physical properties are reported for  $\beta$ -HMX, unless otherwise specified.

**Table 27:** Physical properties of HMX

|                             | SI units               | Other units                  | References |

Data source: [133]

Additional information on properties of HMX is available in other well-known common information sources [239, 241, 243, 423].

### 15.2.1 Melting Point of HMX

The melting point of HMX is 540 K (267 °C), melting higher than its relative, RDX. HMX is frequently contaminated by RDX and vice versa. At other times, HMX is deliberately mixed with RDX to obtain desirable properties of such mixtures. In either case, knowledge of the phase diagram of the binary mixture is important information to have.

Two binary phase diagrams for the RDX/HMX system have been determined experimentally both with first melting mixtures and repeatedly remelting mixtures [294]. Liquidus curves have been predicted computationally for RDX and  $\beta$ -HMX. Mixtures exhibit the thermal characteristics associated with simple binary eutectic systems affected by observable HMX polymorphism. The HMX/RDX system is characterized by two binary eutectics, ideal behavior by the S-RDX component and thermal instability that is associated with liquid RDX and with excess solid  $\delta$ -HMX in the presence of liquid RDX (Figure 22). The melting temperatures associated with the two eutectics are governed by HMX polymorphism with the one melting at the lower temperature (461.6 K = 188.5 °C) involving  $\beta$ -HMX and S-RDX and the one melting at the higher tem-

**Figure 22:** HMX/RDX temperature/composition diagram from initial melting operations. (Republished and modified from [294], with permission from ©2003 Taylor & Francis Ltd., <http://www.tandfonline.com>.)

perature (464.5 K = 191.4 °C) involving  $\delta$ -HMX and S-RDX. The presence of both the  $\beta$ - and  $\delta$ -polymorphs of HMX were confirmed by XRD. The RDX melting temperatures were consistent with calculated liquidus temperatures.

Figure 23 presents a temperature-composition phase diagram of the HMX/RDX binary system at atmospheric pressure [424]. The solid curves represent the phase boundaries from a theoretical model. Figure 23 is an overall, coarse view, but the paper also contains three additional, detailed views where one has zoomed in on locations near the melting temperature of pure RDX, the eutectic point, and the peritectic point. Four single-phase regions are present:  $\beta$ -HMX-rich solid (labeled as  $\beta$ ),  $\delta$ -HMX-rich solid ( $\delta$ ), RDX-rich solid (RDX), and liquid. These four phases combine to form five distinct two-phase regions, each of which is represented by addition of the two constituent phases (e.g., the two-phase region between  $\beta$ -HMX-rich solid and RDX-rich solid is denoted as ( $\beta$  + RDX)). Three-phase equilibria are represented by points which denote the composition of the three phases that are in equilibrium. As a visual aid, the points were connected together with imaginary tie lines. The eutectic tie line connects the eutectic point, which represents the liquid, with points for the  $\beta$ -HMX-rich and RDX-rich solid phases. The peritectic tie line connects the peritectic point, which represents the  $\beta$ -HMX-rich solid, with points for the  $\delta$ -HMX-rich solid phase and

**Figure 23:** Temperature-composition phase diagram of the HMX/RDX binary system at atmospheric pressure. (Reprinted and adapted from [424], with permission from ©2017 American Chemical Society; permission conveyed through RightsLink.)

the liquid phase. Similar phase diagrams for the HMX/RDX system were presented for higher pressures, 500, 1000, 1500, and 2500 bar. The transition temperature increased with pressure more than the melting temperatures do. Consequently, the area of the  $\beta$  + liquid region increased with pressure, but the area of the  $\delta$  + liquid region decreased with pressure. Above 1653 bar, the melting point of  $\beta$ -HMX is lower than the transition temperature so that  $\delta$ -HMX no longer appears in the pure HMX phase diagram. The HMX/RDX system at these higher pressures becomes a simple, binary eutectic system where  $\beta$ -HMX is the only polymorph present. The peritectic temperature that signifies the transition of  $\beta$ -HMX-rich solid to  $\delta$ -HMX-rich solid (and liquid) is absent above 1653 bar.

### 15.2.2 Phase Transitions of HMX

HMX undergoes a series of phase transitions. A distinct feature of HMX is the strongly metastable nature of its polymorphs. Many of its properties change during those transitions. When listing properties of HMX, it is important to specify which of the modifications the properties were obtained for. In most cases the properties will be for  $\beta$ -HMX, unless otherwise specified. The transitions do not happen very quickly; thus, it is possible to obtain properties for  $\beta$ -HMX outside its normal stability range. The HMX phase of primary interest to the military is  $\beta$ -HMX because it has the highest density. There is much ambiguity in the literature regarding the thermodynamic stability of

$\alpha$ -HMX (if it exists at all). The  $\gamma$ -phase is not a true polymorph but rather is a hydrate with a stoichiometric ratio of four HMX molecules per water molecule.

A transition from the  $\beta$ -form of HMX to the  $\delta$ -form was observed at 431 K on heating at atmospheric pressure. This  $\beta \rightarrow \delta$  transition is typically associated with and precedes the thermal decomposition of HMX. The stability to pressure of each polymorph of HMX has been studied using Raman and infrared spectroscopy [425]. The observed behavior of the polymorphic forms is as follows:  $\beta$ -HMX is stable up to 5.4 GPa, and the  $\alpha$ -form is stable up to 4.2 GPa.  $\gamma$ -HMX converts to  $\beta$ -HMX at 0.55 GPa.  $\delta$ -HMX converts to a mixture of  $\alpha$ - and  $\beta$ -forms at pressures below 0.05 GPa. Further studies have shown that the  $\beta$ -form is stable up to 10.0 GPa [426]. Before melting HMX undergoes  $\beta \rightarrow \delta$  modification transition with the heat of transition of 9.83 kJ/mol (2.35 kcal/mol) [245]. See also [427, 428]. The heats of transformation of the four known polymorphic forms of octogen (HMX) were measured calorimetrically as listed in Table 28.

**Table 28:** Heats of transformation of polymorphic forms of HMX.

| Phase transition            | Temperature |         | Heat of transformation |                 |
|-----------------------------|-------------|---------|------------------------|-----------------|
|                             | K           | °C      | kJ/mol                 | kcal/mol        |
| $\alpha \rightarrow \delta$ | 466–474     | 193–201 | $7.41 \pm 0.21$        | $1.77 \pm 0.05$ |
| $\beta \rightarrow \delta$  | 440–456     | 167–183 | $9.79 \pm 0.13$        | $2.34 \pm 0.03$ |
| $\gamma \rightarrow \delta$ | 440–455     | 167–182 | $2.80 \pm 0.08$        | $0.67 \pm 0.02$ |

Data source: [87]

Literature values for the  $\beta \rightarrow \delta$  solid–state transition temperatures of HMX vary over a wide range, for instance, 440–456 K (167–183 °C), 456.9 and 441.9 K (183.8 and 168.8 °C), 422–424 K (149–151 °C), and 459.9 K (186.8 °C), and the literature heat of transition is 9.83 kJ/mol (2.350 kcal/mol).

When examining the thermal behavior of HMX/RDX mixtures by DTA and TGA, it was found that the temperature of polymorphic transformation of HMX showed an increase due to the presence of RDX [429]. The enthalpies of the endothermic transformations depended on the composition of the mixture, and there was a linear relationship up to 30 mass-% RDX. The existence of an eutectic with a composition of 30 mass-% HMX/70 mass-% RDX was postulated to explain the melting processes.

The four phases of HMX and its transitions were investigated using XRD [430, 431]. The phases were heated stepwise in a temperature range from 170 to 510 K, measuring a diffraction pattern after each step. The thermal expansion of the different phases and the volume changes during the phase transitions were obtained. Anomalies and strongly anisotropic expansions were observed with  $\beta$ - and  $\gamma$ -HMX. The highest thermal expansion was found with  $\gamma$ -HMX, followed by  $\delta$ ,  $\beta$ , and  $\alpha$ -HMX. The highest volume change was observed with the  $\beta \rightarrow \delta$  transition, followed by the  $\alpha \rightarrow \delta$  and the  $\gamma \rightarrow \delta$  transition.

The  $\beta \rightarrow \delta$  solid-state phase transition in HMX is thermodynamically first order with a measured latent heat, occurred via nucleation and growth, and exhibited a thermally activated rate of transformation. A two-state kinetic model of the system was constructed consisting of equilibrium terms first order in the  $\beta$  or  $\delta$  mol fraction simulating nucleation, and second order in  $\beta$  and  $\delta$  simulating growth [432, 433]. The model had four rate constants, the temperature dependence of which was described by eight parameters. The model was applied to both the  $\beta \rightarrow \delta$  and  $\delta \rightarrow \beta$  transformations over a temperature range from 300 to 700 K in order to assess the theoretical validity of the model and it reproduced the half-time of the transition over this entire range, spanning conversion times from  $10^6$  to  $10^{-4}$  s.

Complementing a parallel paper on thermodynamics, the transformation kinetics of the  $\beta \rightarrow \delta$  solid-state phase transition in HMX were measured with second harmonic generation of a monochromatic laser beam which provided a very high sensitivity, zero background probe of the  $\delta$  phase concentration [434]. This signal was used as a quantitative measure of the  $\delta$  phase mol fraction in HMX crystals. The spatial characteristics of the transformation were shown to be consistent with nucleation from a low density of initial sites, followed by rapid growth. In a series of isothermal experiments, the kinetic rates of both  $\beta \rightarrow \delta$  conversion and  $\delta \rightarrow \beta$  reversion were examined.

Differential scanning calorimetry (DSC) was used to measure the kinetics of the  $\beta \rightarrow \delta$  solid–solid phase transition of HMX [435]. Integration of the DSC signal gave a direct measurement of the degree of conversion. Data was analyzed by first-order kinetics, the Ozawa method and isoconversional analysis. The range of activation energies found in this work, centering around 500 kJ/mol, was much higher than previously reported values by Brill et al. [393] (204 kJ/mol), and Henson et al. [432] (200 kJ/mol).

The structural, vibrational, and thermodynamic properties of  $\beta$ -HMX crystals were studied using isothermal-isobaric molecular dynamics (NPT-MD) simulations [436]. When examining the variations of cell volume, lattice constants, and molecular geometry of solid  $\beta$ -HMX at different pressure and temperature, it was found that the N–N bond was significantly lengthened with increasing temperature, which suggested that it is relevant to the initial decomposition. An abrupt change was observed at 27 GPa for the volume and internal geometrical parameters. This was in good accordance with the experimental observation that there is a phase transition at 27 GPa, which was clearly due to a conformational change, and not a chemical reaction. The vibrational frequencies at ambient conditions agreed well with experimental results. Frequency discontinuities were observed at the same pressure where the phase transition occurred.

The transformation of a  $\gamma$  polymorph of HMX to a  $\beta$  polymorph is not easy to achieve. In order to obtain  $\beta$ -HMX from  $\gamma$ -HMX, a novel and economical method was developed using hot water [437]. The  $\beta$ -HMX thus obtained was characterized using TGA and DTA, HPLC, FTIR spectroscopy, Raman spectroscopy, and impact sensitivity.

A physical model was developed to describe the phonon density of states for HMX and it was used to calculate a set of thermodynamic properties, such as the thermal expansion coefficient, bulk modulus, specific heat, and the Hugoniot curve [438]. The results were in good agreement with available experiments at low pressure and provided reasonable prediction capability at high pressures where data were not available due to the lack of experiments. Two types of phase transitions were compared: static phase transition and shock-induced phase transition. It was determined that the phase transition curves of the two mechanisms are quite different. The pressure required to induce a phase transition for HMX by shock loading is larger than that under static conditions.

Thermodynamic models were developed for the five most commonly studied phases of HMX: liquid HMX and four solid polymorphs ( $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -HMX) [424]. Graphs derived from these models showed results for the density, heat capacity, bulk modulus and sound speed, as well as a phase diagram that illustrates the temperature and pressure regions over which the various HMX phases are most thermodynamically stable. The models were based on the same equation of state previously used for RDX. This paper has a list of 23 different literature sources for the transformation temperature  $\beta \rightarrow \delta$  of HMX. The temperatures ranged from 430 to 460 K. Both HMX and RDX models were combined together so that the equation of state can also be applied to liquid and solid mixtures of HMX/RDX. This allowed one to generate an HMX/RDX phase diagram and calculate the enthalpy change associated with a few different kinds of phase transitions that these mixtures may undergo. A single equation of state was derived that was capable of modeling both pure HMX and HMX/RDX mixtures. By examining possible arrangements for the relative order of the six different solid–solid transition ( $\alpha - \beta$ ,  $\alpha - \gamma$ ,  $\alpha - \delta$ ,  $\beta - \gamma$ ,  $\beta - \delta$ , and  $\gamma - \delta$ ) temperatures, it was concluded that  $\alpha$ -HMX must be thermodynamically stable so that the HMX phase diagram should have an  $\alpha$  phase region, see Figure 24, which illustrates the phase diagram for HMX at very high pressures..

Equilibrium phase diagram of HMX in Figure 24 was generated by finding the phase with the lowest Gibbs free energy (chemical potential) for a given temperature and pressure. The dashed line shows the extrapolation of the  $\beta - \delta$  curve into the  $\alpha$  phase region. Because of strong nucleation and growth barriers exhibited by the HMX polymorphs, the phase diagram that is observed in practice may look more like one where the  $\beta$  phase region has been extended up to the curve so that the only observable solid–solid transition is  $\beta - \delta$ . See also [267, 439, 440].

### 15.2.3 Vapor Pressure of HMX

HMX exists in four polymorphic forms. Only two of the three published papers on vapor pressure of HMX clearly state the polymorphic form of the HMX used. The vapor pressure measurements by Rosen and Dickinson [248] stated that they have used  $\beta$ -HMX but  $\beta$ -HMX is only stable up to 115°C and most of their measurements were done

**Figure 24:** Equilibrium phase diagram of HMX at high pressures. (Reprinted and adapted from [424], with permission from ©2017 American Chemical Society; permission conveyed through RightsLink.)

above this temperature. This introduces some uncertainty in their data. Taylor [441] made measurements on  $\delta$ -HMX and at a much higher temperature. The critical review by Oestmark et al. looked at data from five papers that had been published on the vapor pressure of HMX and other explosives, trying to resolve discrepancies and trying to establish a baseline for further comparison [254]. The data from these papers are compared in Figure 25 together with fits to the Clausius–Clapeyron equation. The Clausius–Clapeyron fit of the data for HMX led to the equation

$$\log P = A - \frac{B}{T} = 16.1 - \frac{9125}{T}$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin for the temperature range 370–403 K (97–130 °C). The vapor pressure of HMX at 298 K was extrapolated to be  $3.01 \times 10^{-15}$  mm Hg. The heat of sublimation is 174.7 kJ/mol (41.75 kcal/mol).

The Clausius–Clapeyron equations should intersect at the phase transition temperature, but this is not the case. This further indicates that not all data used for this curve fit were reliable. However, the data presented by Rosen and Dickinson is considered the most accurate for calculating HMX vapor pressures at room temperature (Figure 26) [247, 248]. The vapor pressure of  $\beta$ -HMX at 395 K (121.9 °C) is  $10^{-7}$  mm Hg. The slope of the vapor pressure curve in Figure 26 corresponds to a heat of sublimation of 175.3 kJ/mol (41.9 kcal/mol).

**Figure 25:** Vapor pressure of HMX. (Republished and modified from [254], with permission from ©2012 John Wiley & Sons – Journals; permission conveyed through Copyright Clearance Center, Inc.)

The vapor pressure of HMX in the temperature range 461 to 486 K (188 to 213 °C) has been measured by the Knudsen effusion method, and the enthalpy of sublimation over this range was calculated to be 161.9 kJ/mol (38.7 kcal/mol) [441]. Other measurements led to the heat of sublimation of 161.1–161.9 kJ/mol (38.5–38.7 kcal/mol) [256].

Based on the heat of HMX melting, the heat of phase change, and the heat of sublimation, a value 117.1 kJ/mol (28 kcal/mol) was adopted as the heat of HMX evaporation [252]. Starting from this figure and numerous converging data on the surface temperature at atmospheric pressure, a pressure dependence of liquid HMX surface temperature in the range 600–835 K was constructed based on the equation

$$\ln P = 21.717 - 14091.6/T$$

where  $P$  is the pressure in atm and  $T$  is the temperature in kelvin, as shown in Figure 27 [442].

**Figure 26:** Vapor pressure of  $\beta$ -HMX. (Reproduced and modified from [247].)

As part of developing a Peng–Robinson equation of state for HMX, the vapor pressure data from several sources were plotted to derive the coefficients  $a$  and  $b$  for this equation of state [424].

### 15.2.4 Density of HMX

HMX occurs in four crystal structure modifications at atmospheric pressure which all differ in their density. The densities of the four polymorphs are summarized in Table 29.

**Table 29:** Densities of HMX polymorphs

| Modification           | Density, g/cm <sup>3</sup> |
|------------------------|----------------------------|
| $\alpha$ -modification | 1.87                       |
| $\beta$ -modification  | 1.96                       |
| $\gamma$ -modification | 1.82                       |
| $\delta$ -modification | 1.78                       |

Data source: [133]

**Figure 27:** Vapor pressure above liquid HMX as a function of reciprocal temperature. (Republished and modified from [252], with permission of ©2009 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

Dimensional changes related to temperature cycling of the  $\beta$ - and  $\delta$ -polymorphs of HMX are important for a variety of applications. Debonding of crystals from the binder in a propellant, forming voids, might change the burning rate of a propellant. The coefficients of thermal expansion of  $\beta$ - and  $\delta$ -phases were measured over a temperature range of 253 to 488 K (–20 to +215 °C) by thermomechanical analysis (TMA) [443]. Dimensional changes associated with the phase transition were also measured, and the time–temperature dependence of the dimensional change was consistent with phase transition kinetics measured earlier by DSC. One HMX sample measured by TMA during its initial heating and again three days later during a second heating showed the  $\beta$ -to- $\delta$  phase transition a second time, thereby indicating back conversion from  $\delta$ - to  $\beta$ -phase HMX during those three days of storage. DSC was used to measure kinetics of the  $\delta$ - to  $\beta$  back conversion. The most successful approach was to first heat the material to create the  $\delta$  phase, then after a given period at room temperature, measure the heat absorbed during a second pass through the  $\beta$ - to  $\delta$ -phase transition. Back conversion at room temperature followed nucleation–growth kinetics, similar to the forward conversion. The linear coefficient of thermal expansion of HMX in the range 219–347 K is  $5.04 \times 10^{-5} \text{ K}^{-1}$ . The cubical coefficient of thermal expansion of HMX in the range 243–343 K is  $1.625 \times 10^{-4} \text{ K}^{-1}$ .

Isothermal pressure–volume equations of state of  $\beta$ -HMX at temperatures of 303, 373, and 413 K (30, 100, and 140 °C) under both hydrostatic and nonhydrostatic compressions were obtained using synchrotron angle-dispersive XRD [444]. The samples were heated to the isotherm temperature and compressed to up to 5.8 GPa. At all temperatures, HMX remained in the  $\beta$ -phase up to 5.8 GPa. However, at 413 K (140 °C) upon decompression from nonhydrostatic pressures above 4 GPa to ambient pressure, HMX underwent a phase transition to the  $\delta$ -phase. The same transition was seen upon decompression from hydrostatic compression to ambient pressure; however, parts of the sample remained in the  $\beta$ -phase, resulting in a mixed-phase sample. The XRD data were analyzed to yield unit-cell dimensions at each pressure, and further analyzed to yield coefficient of thermal expansion, bulk modulus, and the pressure derivative of the bulk modulus.

The phase behavior of HMX at ambient pressure was investigated by XRD [445]. The XRD patterns at elevated temperature showed that there was a co-existing temperature range of  $\beta$ - and  $\delta$ -phase during the phase transition process. In addition, mechanical forces can catalyze the conversion from  $\delta$ - back to  $\beta$ -phase. Based on the XRD diffraction patterns of  $\beta$ - and  $\delta$ -phase at different temperatures, the coefficients of thermal expansion was calculated by Rietveld refinement. For  $\beta$ -HMX, the linear coefficients of thermal expansion of a-axis and b-axis were about  $1.37 \times 10^{-5}$  and  $1.25 \times 10^{-4} \text{ } ^\circ\text{C}^{-1}$ . A slight decrease in c-axis with temperature was also observed, and the value is about  $-0.63 \times 10^{-4} \text{ } ^\circ\text{C}^{-1}$ . The volume coefficient of thermal expansion was about  $1.60 \times 10^{-4} \text{ } ^\circ\text{C}^{-1}$ , with a 2.2% change from 303 to 443 K (30 to 170 °C). For  $\delta$ -HMX, the linear coefficients of thermal expansion of a-axis and c-axis are found to be  $5.39 \times 10^{-5}$  and  $2.38 \times 10^{-5} \text{ } ^\circ\text{C}^{-1}$ , respectively. The volume coefficient of thermal expansion of  $\delta$ -HMX was about  $1.33 \times 10^{-4} \text{ } ^\circ\text{C}^{-1}$ , with a 2.6% change from 303 to 503 K (30 to 230 °C). The results indicated that  $\beta$ -HMX has a similar volume coefficient of thermal expansion compared with  $\delta$ -HMX, and there is about 10.5% expansion from  $\beta$ -HMX at 303 K (30 °C) to  $\delta$ -HMX at 503 K (230 °C), of which about 7% may be attributed to the reconstructive transition.

The thermal expansion of the  $\beta$ -phase of HMX was studied in the temperature range of 123 to 303 K (−150 to +30 °C) [446].  $\beta$ -HMX is monoclinic with the unit cell parameters of  $a = 6.5255(10) \text{ \AA}$ ,  $b = 11.0369(18) \text{ \AA}$ ,  $c = 7.3640(12) \text{ \AA}$ , and  $\beta = 102.67(1)^\circ$ , space group  $P2_1/n$ . On cooling from room temperature to 123 K (−150 °C) the crystals underwent an anisotropic contraction with the a-axis virtually unchanged, while the b and c axes contract by approximately 1.8 and 0.6%, respectively. The disproportionate change in the a and c axes resulted in approximately a 0.4% change in the  $\beta$  angle. Despite the large differences in expansion along the different axes, no phase change was observed. HMX is more compressible in hydrostatic conditions ( $B_0 = 12.4 \text{ GPa}$  and  $B' = 10.4$ ) than in nonhydrostatic conditions ( $B_0 = 14.4 \text{ GPa}$ ,  $B' = 13.3$ ) [447].

### 15.2.5 Solubility of HMX

HMX is practically insoluble in water. Its solubility in other solvents such as supercritical carbon dioxide is similar to that of RDX, which is very low [272]. It is important to know solubility of HMX if it has to be removed from munitions during demilitarization with a suitable solvent. Solubilities of HMX in different solvents are listed in Table 30.

**Table 30:** Solubility of HMX in organic solvents

| Solvent                                 | Temperature, K |     |                  |                  |     |
|-----------------------------------------|----------------|-----|------------------|------------------|-----|
|                                         | 298            | 303 | 333              | 353              | 371 |

<sup>a</sup> At the boiling point of the solvent

Data source: [273]

In a systematic study of the solubilities of representative explosives in various single and binary solvents, dimethylformamide (DMF) was judged to be a good overall solvent for explosives when factors such as the solubility values, physical properties, cost, availability, convenience, and toxicity of the solvent are considered. However, DMF forms a crystalline solvate with HMX and is not useful as a solvent for HMX [273, 448]. A butyrolactone–dimethylsulfoxide mixture was recommended as a solvent for HMX.

### 15.2.6 Thermal Conductivity of HMX

Thermal diffusivities and thermal conductivities of RDX and HMX were measured from room temperature into the decomposition region by use of a laser flash method [280, 281]. Thermal conductivities were calculated from the thermal diffusivity, specific heat, and density of each material.

The heat capacity, thermal conductivity, and thermal diffusivity of a range of other oxidizers, binders, and rocket propellants were determined and compared to literature

data. The thermal diffusivity  $\alpha$  of HMX for the range from 293 to 443 K (20 to 170 °C) can be described by the linear equation

$$\alpha = 2.62 \times 10^{-3} - 6.74 \times 10^{-6}t$$

where  $\alpha$  is the thermal diffusivity in  $\text{cm}^2/\text{s}$  and  $t$  is the temperature in °C. Likewise, the thermal conductivity  $\lambda$  of HMX for the range from 293 to 443 K (20 to 170 °C) can be described by the linear equation

$$\lambda = 1.19 \times 10^{-3} - 11.5 \times 10^{-7}t$$

where  $\lambda$  is the thermal conductivity in  $\text{cal cm}^{-1} \text{s}^{-1} \text{°C}^{-1}$  and  $t$  is the temperature in °C. Similar data are contained in the same publication for a wide range of oxidizers, binders, and solid propellants. See also [449].

## 15.2.7 Thermodynamic Properties of HMX

### 15.2.7.1 Heat Capacity of HMX

The heat capacity of HMX changes with each change of the crystal structure at one of the phase change transition points. The specific heats of HMX and RDX were measured from room temperature into the decomposition region by use of a laser flash method [280, 281]. At this rapid heating rate, no phase changes are taking place because they are slower. The specific heats of RDX and HMX are graphed for comparison in Figure 10 which was already shown in *Encyclopedia of Oxidizers* chapter “Perchlorate Oxidizers” and earlier in this volume in the section on “RDX.”

Heat capacity of HMX with a density of  $1.900 \text{ g/cm}^3$  in the range 310–440 K (37–167 °C) was

$$c_p = 0.231 + 0.00055t$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{°C}^{-1}$  and  $t$  is the temperature in °C [283]. The mid-range standard deviation was  $0.004 \text{ cal g}^{-1} \text{°C}^{-1}$ .

The molar heat capacity of  $\beta$ -HMX in the range from 200–452 K (–73 to +179 °C) can be described by the following linear equation

$$C_p = (28 \pm 3) + (0.15 \pm 0.009) \times T$$

where  $C_p$  is the molar heat capacity in  $\text{cal mol}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin. The molar heat capacity of  $\beta$ -HMX at 298 K is  $307.9 \text{ J mol}^{-1} \text{K}^{-1}$  ( $73.6 \text{ cal mol}^{-1} \text{°C}^{-1}$ ). Similar data are available for  $\alpha$ -HMX,  $\gamma$ -HMX, and  $\delta$ -HMX.

The heat capacity of HMX for rapid heating in the range from 293–443 K (20–170 °C) can be described by the following linear equation [282]:

$$c_p = 0.230 + 6.60 \times 10^{-4}t$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{°C}^{-1}$  and  $t$  is the temperature in °C.

The specific heat of  $\beta$ -HMX and  $\delta$ -HMX in the temperature range 588 to 718 K (315–445 °C) was determined by DSC [450, 451]. The heat capacities for the two phases of HMX were nearly identical to within 1% (Figure 28). Heat capacities of single crystals were smaller than those of powdered samples. The start of the transformation occurred at 453 and 460 K for the single crystal and for the powdered sample, respectively. Unlike the specific heats, the transformation temperatures were dependent on the heating rate.

**Figure 28:** Specific heat of single crystal and powdered  $\beta$ -HMX and  $\delta$ -HMX. (Reproduced and modified from [450].)

#### 15.2.7.2 Enthalpy of Formation and Heat of Combustion of HMX

The calculated standard enthalpy of formation for HMX as ideal gas in the gas phase is  $275 \pm 30$  kJ/mol and the calculated entropy is  $608.7 \pm 15$  J mol<sup>-1</sup> K<sup>-1</sup> [285]. Based on sublimation measurements, an enthalpy of formation for gaseous HMX was predicted as 248.9 kJ/mol [452]. Table 31 provides a summary of published thermodynamic data for HMX. The enthalpy of formation is different for each of the four modifications of HMX. The transition enthalpies are listed in Table 33.

In addition to experimental calorimetric methods, the gas phase enthalpies of formation and thermodynamic functions of HMX and similar compounds can be calculated using quantum mechanical computational methods [305].

Isochoric upper heats of combustion of HMX are listed in Table 32.

#### 15.2.7.3 Heat of Fusion and Solid-State Phase Transitions of HMX

Because of rapid decomposition at the melting point, direct measurements of heat of melting are difficult to conduct. Using indirect measurements, a value 69.9 kJ/mol

**Table 31:** Standard enthalpy of formation of HMX.

Molecular mass: 296.1551 g/mol = 3.3766 mol/kg

(16.7 kcal/mol) was obtained from the HMX-RDX melting-point diagram [296], while a considerably lower value was measured as the heat of dissolution of HMX in an inert solvent. The heats of dissolution in acetone, butyl acetate, or aniline were very similar and equal to ~26.4 kJ/mol (6.3 kcal/mol).

#### 15.2.7.4 Heat of Sublimation of HMX

The heat of sublimation of HMX is  $\Delta H_{\text{sub}}$  161.9 kJ/mol at 461–487 K [441]. Other sources gave an enthalpy of vaporization of 158.6 kJ/mol at 507 K (234 °C) [453]. See also [296].

#### 15.2.8 Molecular Properties of HMX

HMX occurs in four modifications, of which only the β-modification possesses a particularly high density and hence also a very fast velocity of detonation. The transition temperatures and stability ranges are summarized in Table 33 along with the transition enthalpies.

The crystal structure of α-HMX has been determined by single crystal XRD [454]. α-HMX crystallized in orthorhombic crystals, space group *Fdd2* (= *C*<sub>2v</sub>) with unit cell parameters of *a* = 15.14 Å, *b* = 23.89 Å, *c* = 6.013 Å and eight molecules in the unit cell. The molecules have a bucket-like shape with twofold symmetry. Bond lengths and angle all have normal values, but there are two rather short intermolecular C—O distances of 3.04 and 3.20 Å.

**Table 33:** Transition temperatures and transition enthalpies of HMX.

| Transition                  | Transition temperature |         |         | Transition enthalpy |       |       |
|-----------------------------|------------------------|---------|---------|---------------------|-------|-------|
|                             | K                      | °C      | °F      | kJ/mol              | kJ/kg | cal/g |
| $\alpha \rightarrow \delta$ | 466–474                | 193–201 | 379–394 | 7.40                | 25.0  | 5.98  |
| $\beta \rightarrow \delta$  | 440–456                | 167–183 | 333–361 | 9.8                 | 33.1  | 7.90  |
| $\gamma \rightarrow \delta$ | 440–455                | 167–182 | 333–359 | 2.80                | 9.46  | 2.26  |
| $\alpha \rightarrow \beta$  | 389                    | 116     | 241     | 2.38                | 8.04  | 1.92  |
| $\beta \rightarrow \gamma$  | 427                    | 154     | 309     | 7.0                 | 23.6  | 5.64  |
| $\alpha \rightarrow \gamma$ | —                      | —       | —       | 4.6                 | 15.5  | 3.71  |

Based on neutron diffraction measurements of the positions of hydrogen atoms, all hydrogen atoms in  $\beta$ -HMX are located close to nearby oxygen atoms, a few of which form intramolecular or intermolecular hydrogen bonds of the type C—H $\cdots$ O [455]. Several short intramolecular and intermolecular distances between oxygen and other atoms could be measured by this method. The heavy-atom locations obtained agreed with those from XRD determinations except for slight position shifts of a few atoms.

The crystal structure of  $\delta$ -HMX has been determined by direct XRD methods from counter intensities [456]. The crystals were hexagonal, space group  $P6_1(P6_5)$  with unit cell parameters of  $a = 7.711(2)$  Å,  $c = 32.553(6)$  Å, and  $Z = 6$ . The four C atoms of the eight-membered ring are planar and the molecule has approximate twofold symmetry about an axis perpendicular to this plane through the center of the ring. The shape of the  $\delta$ -HMX molecule is similar to that of the  $\alpha$ -polymorph which has crystallographic twofold symmetry.

The crystal structure of  $\gamma$ -HMX is monoclinic, space group  $Pn$ , with unit cell parameters of  $a = 13.27$  Å,  $b = 7.90(1)$  Å,  $c = 10.95(1)$  Å,  $\beta = 106.8^\circ$ ,  $Z = 2$ ,  $\rho_{\text{XRD}} = 1.82$  g/cm<sup>3</sup>,  $\rho_{\text{m}} = 1.78$  g/cm<sup>3</sup> at 293 K [457].  $\gamma$ -HMX is a hydrate. The two independent molecules in the unit of structure are similar to those in the  $\alpha$ - and  $\beta$ -polymorphs of HMX. Bond distances and angles and intermolecular contacts are similar to those in the  $\alpha$ - and  $\delta$ -polymorphs of HMX. HMX crystal structure data from older sources are summarized in Table 34.

There has been a lot of work done on the molecular structure of heterocyclic nitramines, both experimentally as well as theoretically, to explain the thermal stability and energetic decomposition of materials like RDX, HMX, and CL-20, also in the search for even more stable or even more powerful nitramines than RDX, HMX, or CL-20. For instance, density functional theory calculations were performed to find relationships between the structures and performance of a series of highly energetic cyclic nitramines [458]. An isodesmic reaction method was employed to estimate the enthalpy of formation. The predicted detonation properties were calculated by using the Kamlet–Jacobs equation based on the theoretical densities and heat of formation. Results indicated the N—NO<sub>2</sub> group and aza N atom are effective substituents for enhancing the detonation performance. From the group of

**Table 34:** Crystal structure parameters of HMX polymorphs.

Data source: [241]

cyclic nitramines compounds examined, all except two exhibited better predicted detonation performance than HMX. The decomposition mechanism and thermal stability of these cyclic nitramines were analyzed via the bond dissociation energies. For most of these nitramines, the homolysis of  $N-NO_2$  is the initial step in the thermolysis, and species with bridged  $N-N$  bonds are more sensitive than others. Based on predicted detonation performance and thermal stability, twelve compounds were identified as promising candidates for high energy density materials (HEDMs).

Molecular dynamics calculations have been carried out to study and simulate initial decomposition processes in nitramines, in particular HMX polymorphs and related nitramines, in the crystalline state [459]. Three types of simulations with different conditions were performed to investigate the effect of the crystalline state on the decomposition processes of the molecule. When the simulation was performed with the gas phase value of the equilibrium  $N-N$  bond length but started from the crystallographic

structure as an initial conformation, large amplitude oscillations of the N—N bond lengths were observed in the trajectories. Another simulation, which took the crystal effects into account by adjusting the equilibrium N—N bond length, also showed the large amplitude oscillations of the N—N bond. In this case, it was also observed that excess vibrational energy of N—NO<sub>2</sub> is transferred to another N—NO<sub>2</sub> moiety. These results indicated the importance of compressed N—N bonds in the crystal for triggering the initial decomposition process of nitramines.

*Ab initio* crystal structure calculations based on statistical data on the organic crystal structural classes can predict crystal density of organic nitramines. Numerical calculations were carried out on the known crystal structures of three polymorphs of HMX [460]. The force-field parameters for the nitramine fragment have been improved to obtain the best correspondence between the predicted and observed molecular geometries. The predicted packings were found to be in reasonably good agreement with XRD structural data, while the computed lattice energies were not accurate enough to predict the observed heats of sublimation and the trend of polymorph stabilities. The method was also used to predict the possible crystal structures of eight isomeric azanitroadamantanes and wurtzitanes.

Chemical kinetic simulations of the reactions of HMX require knowledge of its enthalpy, entropy, and heat capacity in the gas phase and condensed phases. While some experimental measurements are available, most available thermochemical information has been obtained by analogy with the smaller species, RDX, and its reaction products. Using the Hartree–Fock method, structures, vibrational frequencies, and bond strengths for the isolated HMX molecule and its two major reaction products were calculated [461]. This, with some available experimental data, allows one to calculate the relevant thermochemical parameters for these species. With this information and some published experimental measurements of sublimation pressure, phase change enthalpies, and heat capacities, some thermochemical data for three condensed phases of HMX ( $\beta$ -HMX,  $\delta$ -HMX, and liquid HMX) were calculated and presented in both the JANAF and CHEMKIN format.

Density functional theory calculations were performed to predict the heats of formation for three eight-membered ring compounds and four six-membered ring compounds via designed isodesmic reactions [73]. In the isodesmic reactions designed for the computation of enthalpies of formation, diethylnitramine (CH<sub>3</sub>CH<sub>2</sub>)<sub>2</sub>NNO<sub>2</sub> and piperidine were chosen as reference compounds. The heats of formation for —NO<sub>2</sub> substituted derivatives are larger than those of —NF<sub>2</sub> substituent groups. Thermal stabilities were evaluated via bond dissociation energies. As a whole, the homolysis of C—NF<sub>2</sub> or C—NO<sub>2</sub> bonds is the main step for bond dissociation of C—NX compounds. Detonation properties of seven compounds were evaluated by using the Kamlet–Jacobs equation based on the calculated densities and heats of formation. It was found that 3,3,7,7-tetrakis(difluoroamino)octahydro-1,5-dinitro-1,5-diazocine (HNFX) and 3,3,5,5-tetrakis (difluoroamino)-1-nitro piperidine (N-nitro TDFAPP), with predicted density of ca. 2.0 g/cm<sup>3</sup>, detonation velocity of about 9.9 km/s, and detonation pressure of 47 GPa, are more energetic than HMX.

## 15.2.9 Optical Properties of HMX

### 15.2.9.1 Infrared Spectra of HMX

The infrared spectra of  $\alpha$ -,  $\gamma$ -, and  $\delta$ -HMX are similar to each other but are substantially different from that of  $\beta$ -HMX in the longer wavelength regions. The IR spectra of HMX published in [462] or [81] were unfortunately not available in a quality that was reproducible (Figure 29). The images were very pale and required substantial re-work by a graphics illustrator.

**Figure 29:** Infrared spectrum of  $\beta$ -HMX crystals. (Reproduced and modified from [81].)

A  $\beta$ -HMX IR spectrum from another source is shown in Figure 30 for comparison.

**Figure 30:** Infrared spectrum of  $\beta$ -HMX. (Reproduced and modified from [244].)

HMX exists in four polymorphs and the IR spectra of the different polymorphs show subtle differences that can be used for the analysis of this chemical [425, 463]. IR spectra of three polymorphs are shown in Figure 31.

**Figure 31:** IR spectra of  $\alpha$ - (*top*),  $\beta$ - (*center*), and  $\gamma$ -HMX (*bottom*) polymorphs. (Reproduced and modified from [463])

HMX crystals (or, quite often, also RDX) are bonded in nitramine rocket propellants and PBXs with a binder. Surface interactions between the nitramine and the binder or bonding agents determine the bond strength and can be examined by IR [464]. FTIR diffuse reflection spectroscopy has been used to characterize the surface of HMX particles treated by two kinds of bonding agents. The spectra of the samples modified by different bonding agents were compared and the band at  $1532\text{ cm}^{-1}$ , due to asymmetrical stretching vibration of the nitro group, was chemically shifted after treatment with coupling agents, indicating hydrogen bond formation between HMX particles and bonding agents.

#### 15.2.9.2 Raman Spectra of HMX

Fourier transform Raman (FTR) spectroscopy employing near-IR laser radiation at  $1.06\mu\text{m}$  as the scattering source has been used to obtain Raman spectra of HMX and propellant formulations containing HMX [310, 311] (Figure 32).

**Figure 32:** Raman spectrum of HMX. (Reproduced and modified from [464])

A comparison of the Raman spectra of RDX and HMX is shown in Figure 15 in Section 12.2.2.

#### 15.2.10 Dielectric Constant of HMX

The dielectric constant of  $\beta$ -HMX at 298 K and 5 MHz is 3.087 [241]. The dielectric constants of the other modifications are slightly different, with 4.671 for  $\alpha$ -HMX and 3.867 for  $\gamma$ -HMX, also at 298 K and 5 MHz.

### 15.3 Chemical Properties of HMX

#### 15.3.1 Reactions with HMX

HMX is underoxidized, but a powerful explosive and a popular ingredient for CMDDB and nitramine propellants. The oxygen balance of HMX is  $-21.6\%$  for combustion to  $\text{CO}_2$ . HMX would be stoichiometrically balanced if one assumed that combustion proceeds only to CO and not all the way to  $\text{CO}_2$ :

#### 15.3.2 Procurement Specifications for HMX

The procurement of HMX, originally governed by MIL-H-45444B (27 February 1974), was superseded by MIL-DTL-45444C (26 November 1996) and is currently governed by MIL-DTL-45444C (26 November 1996) and Amendment 1 (17 April 1999) which specifies two different grades: Grade A with 93% HMX minimum purity, the remainder being RDX, and Grade B with 98% HMX minimum purity, the remainder being RDX. The specification requirements are listed in Table 35.

**Table 35:** HMX specification requirements per MIL-DTL-45444C.

| Requirement                                                                     | Grade A | Grade B |
|---------------------------------------------------------------------------------|---------|---------|
| Alpha HMX, wt. (max)                                                            | 0.1     | 0.1     |
| HMX content (Beta), wt. (min)                                                   | 93      | 98      |
| RDX content, wt. (max)                                                          | 7       | 2       |
| Melting point, °C, (min)                                                        | 277     | 277     |
| Acetone insoluble material, wt. (max)                                           | 0.05    | 0.05    |
| Inorganic insoluble, wt. (max)                                                  | 0.03    | 0.03    |
| Acidity, wt. (max)                                                              | 0.02    | 0.02    |
| Impact sensitivity, cm, ERL <sup>a</sup> , type 12, 2.5 kg, (min), 35 mg sample | 17      | 17      |

<sup>a</sup> Explosives Research Laboratory of the National Defense Research Committee

The  $\alpha$ -HMX content,  $\beta$ -HMX content and RDX content of HMX can be determined by XRD. Acidity can be determined by titration with 0.05 N NaOH and phenolphthalein or methyl red indicator and reported as acetic acid.

#### 15.3.3 Thermal Stability of HMX

##### 15.3.3.1 Slow Decomposition of HMX

In the slow decomposition of HMX in a DTA with simultaneous measurement of off-gassing by a thermoconductivity detector similar to those used in GC, the onset of exotherm was close to the phase change endotherm at 473 K (200 °C) but a peak of the exotherm could not be determined because the sample exploded at 553 K (280 °C)

**Figure 33:** DTA thermogram of decomposition of HMX. (Reproduced and modified from [241])

(Figure 33). The off-gassing (dashed line) increased sharply once the temperature exceeded 523 K (250 °C).

Both traditional thermal analysis techniques and specialized thermal techniques are applied to characterize explosives like HMX or RDX. A review including 135 references discussed pressure measurement techniques, gaseous product analysis, DTA, DSC, TG, combined TG-DTA, and miscellaneous techniques as applied to a variety of explosive materials [316].

In one set of DTA/TGA analyses of HMX, also in comparison to RDX and three other high explosives, the exotherm of HMX decomposition started at 543 K (270 °C), reaching a maximum at 553 K (280 °C) [244].

As part of a multiyear, Multidisciplinary University Research Initiative (MURI) aimed at a better understanding of combustion instability in solid propellant rocket motors, the rates of decomposition and the burning rates of RDX and many other propellant ingredients have been investigated, and models to interpret the experimental results were established [336]. Several of the publications referenced in that report give a good introduction into the mechanisms for HMX decomposition and are included in the discussion here.

Numerous authors have investigated the rates and mechanisms of decomposition of RDX and HMX under slow heating conditions below and above the melting point [465]. The weight loss during the thermal decomposition of HMX that occurs as the temperature is elevated at a constant heating rate can be separated into four elementary processes: (1) induction period, (2) sublimation, (3) first order solid phase reaction, and (4) highly exothermic liquid phase reaction by plotting them against the

logarithm of the heating rate versus the reciprocal temperature. Hydroxymethyl formamide has been shown to be a major product of the liquid phase decomposition, which suggests that the decomposition of HMX in the liquid phase should be initiated by the N—N bond scission but not by C—N bond scission. The weight loss of HMX below the melting point includes three different processes (Table 36).

Based on IR spectra of decomposition products, a likely mechanism for decomposition of HMX proposed by Kimura and Kubota [465] is

The sublimation and thermal decomposition of HMX were studied by means of Langmuir evaporation and effusion mass spectrometry in the temperature range

**Table 36:** Decomposition of HMX analyzed by TGA.

| Phase | Mass loss fraction $\alpha$ | Kinetic loss equation                    |
|-------|-----------------------------|------------------------------------------|
| I     | $< 0.2$                     | $k = 1.2 \times 10^{24} \exp(-66400/RT)$ |
| II    | $0.2 < \alpha < 0.55$       | $k = 2.5 \times 10^7 \exp(-22900/RT)$    |
| III   | $> 0.55$                    | $k = 3.8 \times 10^{23} \exp(-61800/RT)$ |

Data source: [465]

448–548 K (175–275 °C) [466]. Langmuir evaporation and effusion experiments showed that the primary mechanism for thermal decomposition is ring cleavage to two equal 148 amu species. Subsequent decomposition within the effusion cell produced numerous smaller molecules and free radicals due to the further decomposition of the 148 amu fragment. See also [324, 467].

It has been found that in mixtures of RDX and HMX, the melting temperature and also the polymorphic transformation temperature of HMX showed different values from those of the pure compounds [329]. The melting point of RDX decreased considerably. On the other hand, the polymorphic transformation temperature increased. The energy of this transformation depended on the composition of the aforementioned mixture, and it was possible to establish a relationship in a specific range of compositions.

Of particular importance for the study of the decomposition of energetic materials is the simultaneous thermogravimetric modulated beam mass spectrometry (STMBMS) technique. This instrument allows the rate of selected gas phase product formation to be measured as a function of time and temperature [320, 325, 331]. The results of the STMBMS analysis showed that RDX and HMX have similar decomposition mechanisms as well as similar degradation products.

Simultaneous thermogravimetric modulated beam mass spectrometry and time-of-flight velocity-spectra measurements showed that the pyrolysis products formed during the isothermal decomposition of HMX at 484 K (211 °C) were H<sub>2</sub>O, HCN, CO, H<sub>2</sub>CO, NO, N<sub>2</sub>O, methylformamide, C<sub>2</sub>H<sub>6</sub>N<sub>2</sub>O, octahydro-1-nitroso-3,5,7-trinitro-1,3,5,7-tetrazocine, and a nonvolatile residue [326, 468]. The ion fragmentation of HMX as a function of electron energy showed complete fragmentation of the HMX molecular ion for electron energies  $\geq 12.4$  eV. No fragments from the pyrolysis of HMX other than those mentioned above were observed. The mechanism of HMX decomposition can be clarified by using isotope labeling [469]. The common degradation products for both RDX and HMX observed via STMBMS were N<sub>2</sub>O, CH<sub>2</sub>O, NO, H<sub>2</sub>O, and CH<sub>3</sub>NHCHO. Experiments were also carried out on isotopically labeled materials in order to gain additional mechanistic information about which reaction products arise from labeled functional groups in the starting material. Evidence suggested that the first observable product is N<sub>2</sub>O. Since N<sub>2</sub>O is the first observable product, this suggested that the N–N bond is the weakest in the molecule and that approximately 199 kJ/mol (47.5 kcal/mol) is needed to begin decomposition at this site.

The products formed in the thermal decomposition of HMX have been traced by using mixtures of different isotopically labeled analogues of HMX [469]. The isotopic analogues of HMX used in the experiments included  $^2\text{H}$ -,  $^{13}\text{C}$ -,  $^{15}\text{N}$ -, and  $^{18}\text{O}$ -labeled compounds. The fraction of isotopic scrambling and the extent of the deuterium kinetic isotope effect or the different thermal decomposition products and pathways indicated that isotopic scrambling did not occur for the bonds in  $\text{N}_2\text{O}$  and the bonds in  $\text{CH}_2\text{O}$ . Only one of the bonds in N-methylformamide (NMFA) underwent isotopic scrambling. The lack of complete isotopic scrambling of the N—NO bond in ONDNTA may imply that some HMX decomposition occurs in the crystal lattice. The behavior of the DKIE in different mixtures of isotope-labeled HMX suggested that water probably acts as a catalyst in the decomposition. It was obvious that decomposition of HMX in the condensed phase has several reaction pathways.

Detecting the first degradation products during early decomposition is vital because it allows one to determine the specific bonds that break first as well as the order in which the breakage occurs. From this data, one can make kinetic assignments to specific bonds, which aids in determining the overall degradation mechanism. Using model-fitting techniques, for example, an activation energy of 201 kJ/mol (48 kcal/mol) was calculated for the initial decomposition region in HMX [453, 470, 471].

The mechanisms that are used to explain the decomposition of RDX and HMX are based on results from simultaneous TGA modulated beam mass spectrometry (STMBMS) and time-of flight (TOF) velocity-spectra measurements. These methods are used to identify the decomposition products and to determine their formation rates as a function of time during the decomposition of the samples. Both nitramines form  $\text{H}_2\text{O}$ ,  $\text{N}_2\text{O}$ ,  $\text{CH}_2\text{O}$ , NO, and  $\text{CH}_3\text{NHCHO}$  during decomposition. A mononitroso analogue of the parent compound is formed during the decomposition of both materials. The rates of formation of the various pyrolysis products along with the macroscopic and microscopic features of the NVR that is generated during the decomposition of HMX suggest that a major process involved in the decomposition of HMX below its melting point is the formation of bubble-confined pyrolysis products within the HMX particles. The pressure of the gas within the bubbles may range up to 24 MPa (3500 psi). Possible reaction mechanisms that include both the physical location of the reactions and the possible chemical reaction pathways are presented. The results from the STMBMS experiments are consistent with initial fragmentation of the N—N bond of the molecule to form  $\text{NO}_2$  and the subsequent unraveling of the remaining ring to form  $\text{N}_2\text{O}$  and  $\text{H}_2\text{CO}$ . Secondary reactions of the primary decomposition products that occur within the particles are important in determining the identity and the relative rates of gas release of the products from the solid particles. In order to obtain a better understanding of ignition, combustion, or sensitivity properties, a number of new experimental and diagnostic techniques, such as planar laser induced fluorescence (PUP), coherent anti-stokes Raman spectroscopy (CARS), and infrared multiphoton dissociation (IRMPD), are available to probe the

gas phase processes and further the understanding of the gas phase chemistry. Similarly, the development of simultaneous thermogravimetric modulated beam mass spectrometry (SmMBMS) and time-of-flight (MOF) velocity-spectra techniques have enhanced the application of mass spectrometry to probe processes in the condensed phase using evolved gas measurements. An important goal of these experiments was to develop a link between the physical properties and molecular structures of different nitramines and their combustion behavior. The motivation of the work on the condensed phase was to obtain a better understanding of the physical processes and reaction mechanisms that occur, so that the identity and rate of release of the pyrolysis products can be predicted, as a function of pressure and heating rate, based on the physical properties and molecular structure of the material. This information can then be used along with the gas-phase reaction models to correlate modifications of the nitramine ingredients with variations in the overall combustion. Over the past 40 years, many studies have been conducted on the decomposition of HMX and RDX under various conditions. Based on many of these results and the structural similarities of HMX and RDX, the same decomposition mechanisms have been proposed for both materials.

Mass spectral analysis of the decomposition products from HMX below its melting point by Bulusu and Graybush [472] showed the same group of products as observed by Robertson [318]. In addition, they found that the rate of formation of the products varied during isothermal decomposition experiments in a way that can be explained by either the characteristic induction, acceleratory, and decay stages associated with solid-phase decompositions or by invoking autocatalytic behavior. Furthermore,  $^{15}\text{N}$  tracer studies indicated that the  $\text{N}_2\text{O}$  is formed without  $\text{N}-\text{N}$  bond breaking, thus, suggesting that oxygen atom transfer to the  $\text{CH}_2$  group and  $\text{C}-\text{N}$  bond cleavage is an important step in the decomposition. However, since the total nitrogen is not accounted for in these experiments,  $\text{N}-\text{N}$  bond breaking cannot be ruled out as the initial step in the decomposition.

Thermal decomposition of pure HMX showed DSC endothermic peaks at 483 K (210 °C) from  $\beta$  to  $\gamma$  phase transformation and at 558 K (285 °C) from the HMX melting followed by an instantaneous exothermic decomposition leading to a strong peak at 563 K (290 °C) and a very strong DTGA peak at 598 K (325 °C) with a mass loss of 95% [473]. Addition of  $\text{NH}_4\text{ClO}_4$  to HMX caused the decomposition to take place before melting and the decomposition peak was lowered to 503 K (230 °C). This showed that the addition of  $\text{NH}_4\text{ClO}_4$  to HMX increased the decomposition of HMX. Even the minimum concentration of  $\text{NH}_4\text{ClO}_4$  tested (10%) had a strong effect. The addition of  $\text{NH}_4\text{NO}_3$  to HMX resulted in DSC exothermic decomposition peaks at 518 K (245 °C) and 545 K (272 °C), showing a contribution from  $\text{NH}_4\text{NO}_3$  which decomposed near to the decomposition peak of HMX. Addition of  $\text{KClO}_4$ ,  $\text{NaClO}_4$ , and  $\text{KNO}_3$  did not have any effect.

The thermal decomposition of eight linear and seven cyclic nitramines predominantly with methylenenitramine groupings was studied by DSC [40, 474]. For

eleven of these compounds, fusion was observed before decomposition. Linear relationships were found between the onset of peak temperatures of melting of these compounds and the melting points of their aliphatic structural analogues (i.e., hydrocarbon homomorphs). A similar relationship between the corresponding heats of fusion  $\Delta H_m$  was specified. On the basis of these facts, the melting points (in K) and the  $\Delta H_m$  values (in kJ/mol) were predicted for *N*-nitromethyleneimine, (368.5–371.5 and 23.45), 2,4-dinitro-2,4-diazacyclobutane (433.8–436.1 and 26.33), 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX) (463.4–465.2 and 32.10), 1,3,5,7,9-pentanitro-1,3,5,7,9-pentaazacyclodecane (600.3 and 34.93), and *trans*-1,4,5,8-tetranitro-1,4,5,8-tetraazadecaline (555.6–556.1 and 46.40).

Decomposition of organic compounds in the solid phase occurs much more slowly than in the liquid phase. The retardation and stabilizing effect of the crystal lattice can be defined as the ratio of the decomposition rate in the liquid phase to that in the crystalline phase [475].

In the DTA with slow heating, the temperature at the maximum of the exotherm peak is 552 K (279 °C). The kinetic parameters such as decomposition activation energies and the frequency factor of the HMX decomposition reaction were evaluated by nonisothermal differential scanning calorimetry (DSC) techniques [317].

Thermal decomposition of crystalline HMX was modeled using percolation theory to characterize thermal damage [476]. Percolation theory has been used historically to describe fluid flow through a network of permeable and impermeable sites. To describe thermal decomposition, the permeable and impermeable sites were related to broken or unbroken bonds. For HMX,  $N_2O$  groups were treated as sites connected by oxygen and methyl bridges. Bridges connect the  $N_2O$  sites by C–N bonds and by intermolecular attractions between N and O. The gas-phase reaction of  $N_2O$  with  $H_2CO$  was also included in the mechanism. Predictions of thermal stability were compared to time-to-explosion data. The state of the condensed material at ignition can be characterized by finite HMX-fragments of various molecular weights.

A new formulation based on 1,1-diamino-2,2-dinitroethene (DADNE, FOX-7) and HMX (called FOF-5), with the same theoretical performance as Composition B, has been developed by the FOI Weapons and Protection Division, Swedish Defense Research Agency. The thermal stability of HMX did not deteriorate by adding the other explosive [477].

### 15.3.3.2 Rapid Decomposition of HMX

In a literature survey of the physical properties, sublimation, decomposition, ignition, and deflagration of RDX and HMX, the discussion of physical properties included the crystallography of the materials. This discussion was done with emphasis on the polymorphs of HMX and the solid-phase transitions of HMX and the energetics and kinetics of HMX sublimation. The publication also reported values for energetics, kinetics and species of sublimation and thermal decomposition of solid HMX and possible reaction mechanisms [467]. Decomposition species and energetics of liquid decom-

position measured during high heating-rate studies were compared with results obtained from more traditional, controlled slow heating tests. Shock tube experiments enable the fastest rates of controlled and tunable heating. The ignition behavior of HMX showed that when the sample was subjected to an energy flux, several events occurred over time: heating and gasification of the sample, reaction of the pyrolysis products, ignition, and self-deflagration. The dependence of self-deflagration rates as functions of pressure and initial sample temperature  $t_0$  were given over the pressure range  $1 \text{ atm} < p < 50000 \text{ psi}$  and the temperature range  $-150 < t_0 < 1500 \text{ }^\circ\text{C}$ . Scanning electron micrographs showing the surface of samples rapidly quenched, while self-deflagrating showed a rugged and porous surface.

The effect of perturbing selected surface and foam zone reactions characteristic of burning HMX was examined by determining the gas product compositions from carefully controlled fast thermal decomposition ( $> 100 \text{ K/s}$ ) of a thin film of HMX in atmospheres of Ar,  $\text{H}_2$ ,  $\text{O}_2$ , CO, NO,  $\text{NO}_2$ , and  $\text{NH}_3$  [478]. The results were correlated with experimental combustion data and thermochemical modeling studies of nitramines. A consistent picture about some of the probable reactions in the heterogeneous foam and fizz zones emerged, indicating that  $\text{H}_2$ , CO,  $\text{O}_2$ , and NO affect the secondary thermolysis reactions in these zones.  $\text{NH}_3$  appeared to affect both the primary and secondary reactions, while  $\text{NO}_2$  was directly involved in primary decomposition reactions.  $\text{HNC O}$  and  $\text{CH}_2\text{O}$  appeared to be products from secondary condensed-phase reactions. The results suggested that compounds with  $\text{NH}_x$  sites and  $\text{NO}_2$  are catalytically active species for burn-rate modification of nitramine propellants.

Existing models of thermal-mechanical-chemical response of plastic-bonded HMX systems were able to predict time to explosion in a cook-off situation very accurately, to within a degree of the experimental result. However, the chemical network/reaction rates were less constrained, and many networks could achieve the same level of accuracy. Mechanical response modeling could be improved by the inclusion of porosity and surface tension in the solid species in the reaction network [479]. The addition of the reversible sublimation/vaporization reactions to the reaction network provided a nonreactive pathway yielding mass loss in the lower temperature region in TGA experiments. This implied that a lower decomposition rate can achieve the same overall level of mass loss, thus, reducing the effect of gas pressurization which was incorporated in other models.

The transient behavior of confined HMX in response to an intense, external heat flux has been simulated using a detailed kinetic model [480]. The model was spatially one-dimensional, fully transient, and consisted of equations for modeling the solid (condensed) phase HMX, the gas phase, and the surrounding container for fast cook-off conditions. The condensed-phase decomposition reactions were described by semi-global, distributed kinetics. The gas phase kinetics description included a detailed chemistry model for the combustion of HMX. A nonlinear, numerical solution of the partial differential equations resulted in predictions of

temperature, pressure, velocity, and species fractions as a function of position and time. Predicted time-to-ignition was in good agreement with experimentally measured fast cook-off times. Temperature at ignition was found to be a function of heating rate. The predicted ignition delay for fast cook-off was consistent with laser ignition of bare HMX samples. Simulation results depended on accurate boundary conditions applied to the steel container. Pressurization rates were calculated and the model gave insight into the fast cook-off behavior of HMX. The main decomposition pathway was the conversion of HMX into  $\text{H}_2\text{CO}$  and  $\text{N}_2\text{O}$ .

### 15.3.3.3 Decomposition Kinetics of HMX

Principal products formed from HMX or RDX decomposition include  $\text{N}_2\text{O}$ ,  $\text{N}_2$ ,  $\text{H}_2\text{CO}$ ,  $\text{CO}$ ,  $\text{CO}_2$ , and  $\text{NO}$ , including a number of other products such as  $\text{HCN}$ ,  $\text{HCOOH}$ ,  $\text{NO}_2^-$ ,  $\text{NO}_3^-$ , hydroxymethyl formamide  $\text{HOCH}_2\text{NHCHO}$ ,  $\text{H}_2$ , and  $\text{H}_2\text{O}$  [359].  $\text{NO}_2$  appears to be formed, but is so reactive that many failures to report it may well be due to the fact that it disappeared too rapidly due to further reaction. Relative amounts of  $\text{HCN}$  and  $\text{NO}_2$  may increase at high temperature, while  $\text{H}_2\text{CO}$ , etc., will decrease. There are possible unimolecular and bimolecular follow-up reactions determining the  $\text{N}_2/\text{N}_2\text{O}$  ratio and some possible mechanisms for formation of molecular dinitrogen. The most useful aspect of thermal decomposition studies at low temperatures and pressures is to elucidate the types of chemical decomposition processes involved, including minor (at low temperatures and pressures) pathways, in addition to the principal pathways.

A literature review of kinetic parameters for thermal decomposition of HMX and RDX in the homogeneous vapor, liquid, and dissolved states concluded that the decomposition apparently fits first-order kinetics, and a collection of values for Arrhenius parameters for decomposition of HMX and RDX in the gaseous and liquid phases, and for decomposition of RDX in solution in TNT supported that conclusion [481]. Autocatalysis may cause complications in interpreting, extending, or extrapolating kinetic data for these compounds from measurements carried out below their melting points to the higher temperatures and pressures characteristic of combustion.

The effects of pressure and temperature on the thermal decomposition rate of  $\beta$ -HMX in a diamond anvil high-pressure cell were measured by FTIR at pressures up to 6.5 GPa and temperatures up to 583 K [482]. The observed  $\alpha$  (mol fraction of conversion) vs. time curves were sigmoid and followed rate equations based on the theory of nuclei chain formation with branching interference, suggesting an autocatalytic-type reaction. An increase of pressure decreased the rate of thermal decomposition, while temperature increased the rate in typical Arrhenius behavior. The energy of activation decreased with increasing pressure linearly from 501 kJ/mol at 3.6 GPa to 150 kJ/mol at 6.5 GPa. The reactant increased in volume by about 3% in order to achieve the activated state. Between 3.6 and 5.5 GPa, the reaction mechanism was unimolecular and probably involved a ring expansion prior to bond scission. Above 5.5 GPa, the mechanism was bimolecular. The change in molecularity of the kinetics can be explained by

the introduction of strain into the kinetic model. The observed pressure dependences of entropy, activation energies, and volume appear to explain why  $\beta$ -HMX can detonate at high pressures.

To improve the mechanistic understanding of HMX decomposition in the gas phase, an *ab initio* method was used to determine the various unimolecular decomposition channels [483]. Three distinct mechanisms were found: (1) homolytic cleavage of an N–N bond to form  $\text{NO}_2$  ( $M = 46$ ) and an HMX free radical HMR ( $M = 250$ ) which subsequently decomposed to form various products; (2) successive HONO eliminations to give four HONO ( $M = 47$ ) plus a stable intermediate ( $M = 108$ ); (3) O-migration from one of the  $\text{NO}_2$  groups of HMX to neighboring C atom followed by the decomposition of the intermediate ( $M = 296$ ) to INT222 (a ring-opened RDX structure) and  $\text{CH}_2\text{NNO}_2$  ( $M = 74$ ), which can undergo dissociation to smaller mass fragments. The decomposition scheme for HMX is similar to that for RDX presented earlier [366], except that concerted decomposition of HMX to four methylenenitramines,  $\text{CH}_2\text{NNO}_2$  ( $M = 74$ ) molecules is not a favorable decomposition pathway, whereas this pathway was found in RDX decomposition (both experimentally and theoretically). The formation of RDR-o in the N–N homolysis pathway 1 or the formation of INT222 in pathways 1 and 3 presents a unified mechanistic scheme for the decomposition of both of these nitramines. The HMX decomposition mechanism correlated with available condensed phase experimental results, but detailed comparison of the predicted gas phase energetics was not possible.

A theoretical study of the decomposition mechanism of gas-phase  $\alpha$ -HMX examined four distinct reaction pathways using density functional theory methods [484]. These four distinct reaction channels were included the following: (1) HMX first loses an  $\text{NO}_2$  to form a free radical HMR which further breaks a C–N bond to form a chain structure and then later loses three methylenenitramines (MN,  $\text{H}_2\text{CNNO}_2$ ) successively; (2) the chain structure forms a 10-member ring via a rung closure step before undergoing further decomposition; (3) HMX first eliminates an HONO, then loses two MN, and eliminates an HONO successively; (4) HMX eliminates two HONO successively, then loses an MN, and finally eliminates an HONO. The rate constants of each elementary reaction were calculated using the transition state theory. The thermodynamic properties were calculated for the stable species by employing a standard statistical thermodynamics method. Pathway (1) was found to be the preferred decomposition pathway on the basis of the analysis of rate constants of the elementary reactions.

The laser-induced ignition response of HMX has been investigated using a detailed numerical model [485]. The model was one-dimensional, fully transient, and solved the conservation equations for both the condensed and gas phases. The condensed phase representation included radiation absorption, solid-phase transitions, melting, evaporation, and distributed semi-global decomposition kinetics. The gas phase used a detailed kinetic mechanism to predict species formation

and destruction. Ignition occurred in the gas phase and the flame propagated back toward the surface of the HMX in what is known as the “snap-back” effect. The model then transitioned to steady-state combustion. Calculations were performed in which the solid HMX was irradiated with heat fluxes ranging from 50 to 1600 W/cm<sup>2</sup>. Results were compared to empirical data for the laser-induced ignition of HMX. Good agreement with these data and other steady-state data (burning rate, surface temperature, melt thickness) provided the necessary validation of the developed model.

As part of an evaluation of kinetic data of energetic materials in combustion waves in the calculations for HMX, the average specific heat  $c_p$ , thermal conductivity  $\lambda$ , and density  $\rho$  of sample, were taken as  $c_p = 1.8 \text{ kJ kg}^{-1} \text{ K}^{-1}$  ( $0.43 \text{ cal g}^{-1} \text{ K}^{-1}$ ),  $\lambda = 2.6 \times 10^{-2} \text{ kJ s}^{-1} \text{ m}^{-1} \text{ K}^{-1}$  ( $6.3 \times 10^{-4} \text{ cal s}^{-1} \text{ cm}^{-1} \text{ }^\circ\text{C}^{-1}$ ), and  $\rho = 1.75 \text{ g/cm}^3$ , respectively. According to DSC studies, heat of reaction in the melt at fast heating,  $Q$ , is equal 1387 kJ/kg (331.5 cal/g). Figure 34 illustrates comparative analyses between kinetic parameters of the leading reactions during combustion and thermal decomposition of HMX based on data taken from the literature [252]. HMX decomposition kinetics have been taken for the molten substance (Line 3 from [486] and Line 5 from [3099]) and its solution in dinitrobenzene (Line 2 from [487]) or acetone (line 4 from [38]). As can be seen in Figure 34, kinetic parameters of liquid HMX decomposition derived from the hot combustion model, for the range 660–810 K expressed by the following equation

$$k = 10^{16.78} \cdot \exp(-23440/T)$$

where  $k$  is the kinetic rate in s<sup>-1</sup> and  $T$  is the temperature in kelvin, are in a good agreement with the experimental rate constants of HMX thermal decomposition in the melt and solutions obtained at much lower temperatures.

Based on the data available, it was concluded that the first step of decomposition always includes cleavage of the N–NO<sub>2</sub> bond, which is followed by various secondary reactions and sometimes by chain reactions [43]. A complete understanding of the effects of structures of nitramines on their stabilities is extremely valuable for the synthesis of nitramines with improved performance.

Thermal decomposition of HMX between 448 and 473 K (175 and 200 °C) was studied using the simultaneous TGA modulated beam MS with focus on initial stages of the decomposition [488]. The initial stages of the decomposition have an induction period followed by two acceleratory periods. Arrhenius parameters for the induction period and two acceleratory periods were:  $\log A = 18.2 \pm 0.8$ ,  $E_a = 202 \pm 7 \text{ kJ/mol} = 48.2 \pm 1.8 \text{ kcal/mol}$ ;  $\log A = 17.15 \pm 1.5$  and  $E_a = 205 \pm 13 \text{ kJ/mol} = 48.9 \pm 3.2 \text{ kcal/mol}$ ;  $\log A = 19.1 \pm 3.0$  and  $E_a = 218 \pm 26 \text{ kJ/mol} = 52.1 \pm 6.3 \text{ kcal/mol}$ . These data can be used to calculate the time and temperature required to decompose a desired fraction of a test sample assessing the effect of thermal degradation on sensitivity or burning rates. It can also be used to estimate the extent of decomposition expected under

**Figure 34:** Comparison of kinetic parameters of the leading reaction of HMX combustion (1, data points and dashed line) and decomposition in solutions of dinitrobenzene (2), acetone (4), and in the melt (3 and 5). normal storage conditions for munitions containing HMX. These data, along with previous mechanistic studies conducted at higher temperatures, suggested that the process that controls the early stages of decomposition of HMX in the solid phase is scission of the N–NO<sub>2</sub> bond, reaction of the NO<sub>2</sub> within a lattice cage to form the mononitroso analogue of HMX, and decomposition of the mononitroso HMX within the HMX lattice to form gaseous products that are retained in bubbles or diffuse into the surrounding lattice.

It was assumed that mixtures of HMX and NTO would be less sensitive and more stable than HMX alone. A complete set of possible mechanisms was elaborated theoretically for thermal decomposition of HMX and NTO and for the bicomponent mixtures of both [489]. Initially, the thermal decomposition of HMX was simulated independently. Scheme I shows the routes of HMX thermolysis that are formally possible at the first stage of decomposition.

Scheme I for HMX decomposition. (Modified from Petukhova et al. 2010)

Subsequent stages of decomposition can be represented by chains of intermediates consisting of successive transformations generated along routes 1 and 2 in Scheme I. The observed products of HMX thermal decomposition in the gaseous phase almost entirely consist of simple compounds, such as HCN,  $\text{N}_2\text{O}$ ,  $\text{H}_2\text{O}$ ,  $\text{NO}_2$ , NO,  $\text{H}_2\text{CO}$ ,  $\text{CO}_2$ , and CO. Earlier, it had generally been assumed that the most likely initiating step in the decomposition is N—N bond cleavage, but investigations using  $^{15}\text{N}$  labels indicate that N—N bonds are preserved until  $\text{N}_2\text{O}$  formation. The Petukhova scheme

above does not have the aldehyde —CHO fragments shown in the earlier HMX decomposition scheme proposed by Kimura and Kubota [465]. A computational analysis of the decomposition of the HMX/NTO bicomponent system concluded that decompositions take place independently of each other, with subsequent collisions and interactions of the resultant intermediates and decomposition products. That is, these substances do not interact with each other at the first stage of decomposition, and therefore the scheme thus obtained represents the additive behavior of their thermolysis. See also [490].

#### 15.4 Strand Burning of HMX

For strand burning of RDX, the literature reviewed in this chapter had been divided into experimental and theoretical studies. For HMX, in the following section, we have included both types of studies in the same section, listed here in chronological order.

Data which describe the deflagration rates of HMX single crystals as a function of pressure and initial sample temperature were input into a modification of the Beekstead, Derr, and Price combustion model and values of combustion parameters were predicted with some accuracy [491].

The burning rates for HMX pressed pellets were measured in a windowed bomb burner over a wide range of initial sample temperatures and chamber pressures between 173 and 299 K (−100 and +26 °C) and pressures from 241 kPa to 6.2 MPa (35 to 900 psia) [492]. When added to earlier datasets, the complete dataset spans portions of the range of temperature between 173 and 423 K (−100 and +150 °C) and pressures between 0.1 and 55 MPa (15 and 8000 psia). The pressure exponent was essentially constant at  $0.86 \pm 0.01$  for temperatures equal to or below 273 K (0 °C) and pressures below 6.8 MPa (1000 psia) and dropped with increasing temperature to 0.66 at 423 K (150 °C). If the temperature sensitivity is assumed to be independent of initial temperature, then it is a decreasing function of pressure, being about 0.13%/°C at 6.2 MPa (900 psia) and about 0.45%/°C at 0.69 MPa (100 psia).

Similar experiments were conducted with formulated propellants containing RDX or HMX with and without deuterium isotope labeling [493–495].

Burn rate comparison of HMX and its deuterium labeled HMX-d(8) isotopologue revealed a primary kinetic deuterium isotope effect at 3.55 MPa (500 psig) and 6.99 MPa (1000 psig) pressure and selectively identified covalent carbon–hydrogen bond rupture as the mechanistic step which ultimately controls the further HMX burn rate under the static combustion conditions [496]. The isotope effect further suggested that a rate-limiting C–H bond rupture occurs during the solid-state HMX decomposition/deflagration portion of the overall combustion event.

Two alternative schemes for the combustion chemistry of HMX were proposed and simplifying assumptions were made to achieve a closed-form solution for the condensed phase and three model versions differing in complexity for the gas phase [497].

It was concluded that the combustion is controlled by vapor-phase decomposition and that it would be difficult to achieve large burning rate increases by catalysis. For this particular problem, it would be permissible to neglect mass diffusion in the conservation equations in the interests of computational convenience, but energy diffusion cannot be neglected except for limited purposes.

A steady-state one-dimensional combustion model was used to describe the slow burning deflagration of HMX [498]. The model employed a detailed set of elementary reactions, but only for gas-phase reactions. Different mechanisms were proposed and some of the more important gas-phase reactions were identified. It was hoped that catalytic acceleration of certain reactions would increase the burn rate and regression rate. Observation of the spectroscopic signature of C—N bonds should help in distinguishing different decomposition mechanisms.

The combustion wave structure and thermal decomposition process of HMX were examined in order to elucidate the burning rate characteristics of HMX [499]. According to this experiment, the combustion wave can be divided into three zones: (1) non-reactive solid-phase, (2) surface reaction, and (3) gas-phase reaction zones. Measurements with microthermocouples revealed that the heat flux produced in the surface reaction zone is approximately equal to the heat flux transferred back from the gas phase to the burning surface. Accordingly, the reactions in the surface reaction and the gas phase zones play a dominant role in the burning rate of HMX. The gas phase reaction zone consists of a two-stage reaction: the first stage is the exothermic rapid reaction between  $\text{NO}_2$  and aldehydes, and the second stage is the exothermic slow reaction between  $\text{NO}$  and  $\text{N}_2\text{O}$  and remaining fuel species. The luminous flame zone which is determined to be the second stage reaction rapidly approached the burning surface as pressure was increased. However, the luminous flame reaction appeared to have less of an effect on the burning rate of HMX. Examinations of the quenched burning surface of HMX samples revealed that the burning surface melts and forms a noncrystallized intermediate material. The surface structure appeared to be different from the structure of thermally degraded HMX samples which were obtained by a thermogravimetric analysis. See also [500].

A three-phase, one-dimensional RDX model was extended to HMX [501]. All model inputs were determined independent of the model except for the heat capacity and thermal conductivity of HMX liquid, for which no experimental data were found. Reasonable correlation with experimentally determined burn rate, surface temperature, adiabatic flame conditions, melt layer thickness, and some gas-phase species concentration profiles was achieved using this model. Sensitivity analyses indicated that the adiabatic flame conditions are controlled by thermodynamic properties of the solid and liquid phases. The surface temperature is controlled by the vapor pressure correlation, and the burn rate is largely controlled by the heat feed-back from the gas-phase flame, or the gas-phase mechanism. Sensitivity analyses indicated that differences noted in combustion characteristics of HMX and RDX are likely caused by differences

in vapor pressure and melting temperature, while the similarity of burn rate data was attributed to the similarity of the gas-phase flames. See also [395].

Measurements of strand burning rates of HMX in the range of 1–4 atm, with and without modulated laser augmenting irradiation, showed that in the pressure range of 1–3 atm the HMX combustion had a pronounced auto-oscillating character [385]. Under harmonically modulated radiant flux, the response of reactive force for HMX displayed a resonance character. Even at small modulation intensities, the character of this response was nonlinear. For both HMX and RDX, the dependencies of the steady-state burning rate on initial temperature and on external radiant flux have been determined.

Species and temperature profiles were measured in the gas phase of laser-assisted combustion HMX flames at heat fluxes of 100 and 300 W/cm<sup>2</sup> [383]. A microprobe/triple quadrupole mass spectrometer was used to measure quantitative species profiles, and fine wire thermocouples were used to measure temperature profiles. The flame and surface structures were observed using a high-magnification video system. The major species at the surface were H<sub>2</sub>O, H<sub>2</sub>CO, HCN, NO<sub>2</sub>, N<sub>2</sub>O, N<sub>2</sub>, CO, and NO at atmospheric pressure with both heat fluxes. No CO<sub>2</sub> was detected at the surface. The mol fraction of triazine was found to be approximately 2.5% at the surface, which had not been reported during normal combustion of HMX. This species could play an important role in the gas phase chemistry. The species profiles showed two-stage reaction zones. The species profiles also showed that increasing heat flux stretched the secondary reaction zone, but did not stretch the primary reaction zone. No plateau at a typical dark zone temperature was observed for either heat flux.

The laser- and pressure-driven oscillatory thrust responses of burning HMX at pressures near 1 atm were measured during laser-supported combustion at mean CO<sub>2</sub> laser heat fluxes of 35 and 60 W/cm<sup>2</sup> [502]. During laser-driven testing, the laser flux was modulated at  $\pm 15$  W/cm<sup>2</sup> at driving frequencies ranging from 4 to 250 Hz. Thrust measurements were made with a 10% peak-to-peak variation about the mean chamber pressure at driving frequencies ranging from 4 to 100 Hz. Measured steady-state temperature profiles and numerical predictions of the temperature profiles in the gas-phase reaction zone were used to estimate steady and unsteady heat feedback, respectively. The experimental results were compared to predictions of an analytical model, which used one-step reactions in the condensed phase and gas phase, and numerical modeling results that used detailed gas-phase kinetics. The agreement between the analytical model and the data was found to be better than that between the numerical modeling and the data.

RDX and HMX have similar structures and strand burning rates. As already discussed above, the burning-rate temperature sensitivity  $\sigma_p$  is significantly different between RDX and HMX at low pressure. Efforts to mathematically model the steady-state burning of RDX and HMX with detailed chemical kinetics in the gas and decomposition in the condensed phase all have underpredicted the  $\sigma_p$  trends of HMX at low pressure and have not differentiated between the  $\sigma_p$  values of RDX and HMX. RDX

and HMX both burn with a thin multiphase surface of bubbles in the liquid melt layer. A liquid–bubble model was developed to improve  $\sigma_p$  predictions [397].

The species concentration distribution profiles in HMX flames during combustion in air at a pressure of 1 atm were measured using molecular beam mass spectrometric sampling [398, 399, 503]. HMX vapor was detected near the burning surface for the first time. A total of 11 species were identified in the HMX flame ( $H_2$ ,  $H_2O$ , HCN,  $N_2$ , CO,  $H_2CO$ , NO,  $N_2O$ ,  $CO_2$ ,  $NO_2$ , and HMX vapor), and their concentration profiles were measured. The HMX combustion was unstable. The species concentration profiles exhibited periodic pulsations related to variations in the HMX burning rate. The HMX flame structure at various distances to the burning surface was determined using the average value of the burning rate. There were two main zones of chemical reactions in the flame: In the first zone  $\sim 0.8$  mm wide adjacent to the burning surface, HMX vapor decomposed and  $NO_2$ ,  $N_2O$ , and  $H_2CO$  reacted with each other to form HCN and NO. In the second zone  $\sim 0.8$ – $1.5$  mm wide, HCN was oxidized by nitric oxide to form the final combustion products. The composition of the final combustion products was also analyzed. Using experimental data, gross-reactions for the gasification of nitramines at atmospheric pressure were determined:

The same method was also applied to formulated propellants of RDX or HMX with GAP as the binder [400].

The microstructure and burning parameters of HMX by itself as a solid monopropellant and 25%Al/75%HMX energetic systems as a function of the particle size were examined [504]. Two types of HMX particles, microsized (mHMX) and ultrafine ( $\mu$ HMX) and aluminum powders (micro- and ultrasized (ALEX<sup>TM</sup>)) were used. Morphology and particle size were examined by atomic force microscopy (AFM), SEM, and Brunauer-Emmet-Teller (BET) active surface area analysis. It was shown that the HMX monopropellant's burning rates of the micro- and ultrasized HMX were almost identical in the pressure range 20–100 atm.

The temperature sensitivity of the HMX strand burning rate increased with increasing initial temperature at pressures of 0.1 to 10 MPa, which is typical for combustion of substances with the leading reaction in the condensed phase (c-phase model) [505, 506]. The sample diameters were 7 mm at 0.5 and 1 MPa and 10 mm at subatmospheric pressures. As seen in Figures 35 and 36, the HMX burning rates obtained in different laboratories are in good agreement, and the curve  $r_b = f(p)$  had a slight inflection at  $p = 13$ – $15$  MPa.

The data from all sources can be described by the equation

$$r_b = P^n$$

**Figure 35:** Strand burning rate of HMX at high pressure. (Republished and modified from [506], with permission of ©2009 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

where  $r_b$  is the burning rate in mm/s and  $P$  is the pressure in MPa, with  $n = 0.77 - 0.82$  in the pressure range 0.2–10 MPa and with  $n = 0.9 - 1.1$  in the range of pressures above 10 MPa. Experimental values of the temperature sensitivity of the burning rate in the pressure interval between 1 and 10 MPa are shown in Figure 37.

Experimental values of the temperature sensitivity of the burning rate in the pressure interval between 0.1 and 1 MPa were higher than the values predicted by the c-phase model, but this fact indicated a transition of the combustion process to another regime rather than being a result of combustion instability in this area. The flame structure of burning HMX with different additives was studied with the help of thin tungsten–rhenium thermocouples in the pressure range from 0.025 to 1 MPa. The gas-phase flame was found to ignite in an inductive mode, at least up to a pressure of 1 MPa. The surface temperature was measured as a function of pressure on the basis of experimental data in a wide range of pressures:

$$\ln P = 21.72 - 14092/T$$

where  $P$  is the pressure in atm and  $T$  is the temperature in kelvin. Two possible reasons for the oscillatory regime of HMX combustion observed at atmospheric pressure

**Figure 36:** Strand burning rate of HMX at low pressure. (Republished and modified from [506], with permission of ©2009 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

were proposed: the emergence of resonance phenomena during combustion of an inhomogeneous gas mixture in the tube and the lack of correspondence between the chemical reaction rate in the gas phase at the instant of the resonance and its energy capabilities, which do not allow a necessary HMX gasification rate to be ensured. A mechanism proposed for a wide range of pressures up to 10 MPa was assumed to be based on the leading role of HMX decomposition in the melt at the surface temperature. Strand burning rates of HMX with addition of 5% RDX supported this theory.

Microthermocouples were used to investigate combustion waves of RDX and HMX and the possibilities of mass spectrometer (including gas sampling) and optical techniques of studying the chemistry of gas-phase processes in the combustion wave were analyzed [507].

Another mechanism for HMX combustion was proposed and a corresponding model was developed under the assumption that the combustion wave consisted of two zones, with consideration given to the reaction of decomposition and vaporization of the initial energetic material in the condensed phase and the subsequent decomposition of its vapor in the gas phase [508, 509]. An analysis of the results showed that, at low pressures, the burning rate was largely determined by the

**Figure 37:** HMX strand burning rate versus the initial temperature at different pressures. (Republished and modified from [506], with permission of ©2009 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

exothermic decomposition of the material in the condensed phase, but at pressures above 2.02 MPa (20 atm), the processes in the gas phase began to play an increasingly important role, where the limiting process was the bimolecular activation reaction with the subsequent dissociation of HMX accompanied by secondary reactions between the products. A comparison of the calculation predictions with experimental data showed that the model adequately described a number of characteristics of the combustion wave and ballistic properties, such as the burning rate and its sensitivity to pressure and initial temperature.

Temperature dependences of a number of physicochemical and thermophysical properties of HMX, such as the heat capacity of the liquid phase, change in the enthalpy due to heating of the condensed phase to a predetermined temperature, heat of evaporation, saturated vapor pressure, and the vapor diffusion coefficient in low-molecular-weight gases were calculated in an effort to develop more accurate models for HMX combustion in propellants [510]. The data obtained were used to calculate the amount of heat needed to heat the condensed phase to the burning surface temperature in the range of 560–900 K at various degrees of decomposition. The heat of decomposition of HMX under combustion conditions was calculated from the known

composition of the reaction products at a pressure of 1 bar. This was compared to measured HMX decomposition by DSC. The results of the calculations and experiments suggested that at a degree of decomposition  $\alpha \geq 0.6$ , heat release in the condensed phase can provide heating and evaporation of HMX without heat input from the gas phase. It was shown that the calculated saturation vapor pressures of HMX, which are higher than those presented in the literature, are in better agreement with available experimental data on the HMX vapor concentration profile near the burning surface.

An overview of the papers on the combustion mechanism of HMX published in Russian journals during the time period 2008–2010 attempted to explain the causes of different interpretations of experimental and theoretical results [511]. Based on the analysis, it was concluded that the most reasonable mechanism for HMX combustion is the mechanism which assumes the leading role of the decomposition reaction in the melt at the surface temperature over a wide range of pressures.

## 15.5 Safety Properties of HMX

### 15.5.1 Impact Sensitivity of HMX

It is assumed that the impact sensitivity data reported in the literature and reiterated here are for the 50% point determined by the Bruceton up-and-down method. In the BAM test apparatus, the impact sensitivity of  $\beta$ -HMX is 74 N m [133]. The  $\delta$ -phase, which may occur after heating, is much more sensitive to impact or friction. In the AWRE tester with the No. 12 tool and a 5-kg weight, the 50% point was at 33 cm.

In the Bureau of Mines apparatus with a 32-mg sample, the impact sensitivity is 32 cm with a 2-kg weight [291]. In the Picatinny Arsenal tester with a 23-mg sample, the impact sensitivity is 22.9 cm = 9 in.

The published literature on shock sensitivity of granular explosives like RDX or HMX presents a somewhat confusing picture. A particular problem is that the results of different studies often cannot be directly compared due to the different experimental methods and purity of the samples used to determine sensitivity. Some experimenters do not state which crystal polymorph modification of HMX was being tested.

The  $\beta \rightarrow \delta$  phase transition in HMX has been implicated as the primary reason behind the increased sensitivity of the explosive as it is heated. Both physical and chemical changes accompany the transition, but no study has conclusively shown which specific change, or set of changes, is responsible. A review of the data showed that the mechanical differences, in and of themselves, do not result in increased sensitivity to shock compression of HMX [512].

HMX exists in a variety of crystal structures; the most widely used being the  $\beta$ -phase which is stable at room temperature and pressure. On heating, a more impact sensitive form ( $\delta$  phase) is produced. The nonlinear optical technique of second harmonic generation can be used as a probe of phase since  $\delta$ -phase HMX generates a second harmonic at 532 nm when 1064 nm laser light is incident upon

it. High-speed photography of second harmonic generation in HMX samples during drop weight impact showed that this technique can provide good spatial information and time resolution. There was evidence for small areas of  $\delta$ -phase HMX appearing in the period from 13  $\mu$ s before ignition to 10  $\mu$ s afterwards, demonstrating that the heating on impact is sufficient to overcome the loading conditions and cause the phase change [513].

#### 15.5.2 Card Gap Sensitivity of HMX

Quantum-mechanical based multiscale simulations to study the initial chemical processes of condensed-phase HMX under shock wave loading based on density functional theory methods showed that the initial decomposition of shocked HMX is triggered by the N—NO<sub>2</sub> bond breaking under the low velocity impact (8 km/s) [514]. As the shock velocity increased (11 km/s), the homolytic cleavage of the N—NO<sub>2</sub> bond was suppressed under high pressure, and the C—H bond dissociation became the primary pathway for HMX decomposition in its early stages. It was accompanied by a five-membered ring formation and hydrogen transfer from the >CH<sub>2</sub> group to the —NO<sub>2</sub> group. Simulations suggested that the initial chemical processes of shocked HMX are dependent on the impact velocity, which give new insights into the initial decomposition mechanism of HMX upon shock loading at the atomistic level.

#### 15.5.3 Friction Sensitivity of HMX

In the BAM friction sensitivity test apparatus,  $\beta$ -HMX shows a reaction (crackling) at a pistil load of 120 N. In an effort to identify mutual relationships between friction and impact sensitivities of cyclic nitramines,  $\beta$ -HMX impact and friction sensitivity data were used to demonstrate the potential correlation [515]. Inclusion of an additional 12 nitramines into this scenario resulted in a series of partial relationships, which were correlated with the molecular structure of these substances. It was also found that there is a relationship between increasing heats of fusion of the nitramines studied and their decreasing friction sensitivity numbers. Comparison of friction sensitivity with heats of fusion of the studied nitramines showed that the increase in the heat of fusion values is more or less connected with a decrease in friction sensitivity.

The friction sensitivity of five linear and eight cyclic nitramines was determined and compared to the Arrhenius parameters of nonautocatalyzed thermal decomposition of these nitramines [516]. Generally, increasing values of activation energies of nonautocatalyzed decomposition of these nitramines were shown to be connected with decreasing friction sensitivity numbers.

As a next step of the comparative investigation, friction sensitivities of HMX and similar cyclic nitramines were compared to their detonation velocities to determine whether there was a correlation [517]. For the nitramines studied, these comparisons showed a general trend of friction sensitivity decreasing to smaller numbers with increasing energy content.

#### 15.5.4 Autoignition Temperature of HMX

The autoignition (autoexplosion) temperature of HMX is 0.1 s at 658 K (385 °C), 5 s at 600 K (327 °C), and 10 s at 579 K (306 °C) ([84] p. 173).

### 15.6 Explosive Performance of HMX

In the lead block test, the increase of the cavity volume is  $480 \text{ cm}^3/10 \text{ g}$ . The detonation velocity of confined  $\beta$ -HMX is  $9100 \text{ m/s}$  at  $\rho = 1.9 \text{ g/cm}^3$  [133]. In the Trauzl lead block test, the indentation of HMX was 145% that of TNT.

The ballistic mortar performance of HMX was calculated by a simplified method and compared to experimental measurements. The ballistic mortar performance of HMX was predicted to be 151% of that of TNT and measured as 150% of that of TNT [88].

#### 15.6.1 Detonation Velocity of HMX

The measured detonation velocity of HMX is  $9.11 \text{ km/s}$  at a density  $\rho = 1.89 \text{ g/cm}^3$  and the calculated Chapman-Jouguet (C-J) pressure is 387 kbar at a density of  $\rho = 1.90 \text{ g/cm}^3$  [241]. Other sources gave a detonation velocity of  $9124 \text{ m/s}$  at a packing density of  $1.84 \text{ g/cm}^3$  [84].

#### 15.6.2 Critical Diameter of HMX Detonations

By using wedge-shaped charges and using critical thickness to characterize detonation wave propagation, an experimental study was carried out to explore the effect of particle size of HMX on detonation wave propagation of HMX and HMX/F2641 at two different packing densities of HMX [518]. Experimental results showed the following: (1) a decrease in size of HMX particle resulted in decrease of critical thickness, namely enhancement of detonation wave propagation capability; (2) HMX/F2641 excelled HMX in detonation wave propagation capability at the same size of HMX particles; and (3) an increase of charge density is advantageous to detonation wave propagation.

## 16 Fused Ring Nitramines

### 16.1 Bicyclo-HMX

Bicyclo-HMX, also known as “bicycle”-HMX, 1,3,4,6-tetranitro-2,3a,5,6a-tetrahydroimidazo[4,5-d]imidazole, 1,3,4,6-tetranitrooctahydroimidazo[4,5-d]imidazole,  $\text{C}_4\text{H}_6\text{N}_8\text{O}_8$ , CAS RN [473796-67-7],  $M = 294.139$ , is a thermally stable HMX analog.

Bicycle-HMX

### 16.2 1,4,5,8-Tetranitro-1,4,5,8-tetraazadecalin

An intermediate in the synthesis of *trans*-1,4,5,8-tetranitro-1,4,5,8-tetraazadecalin, 1,4,5,8-tetranitro-2,3,4a,6,7,8a-hexahydropyrazino[2,3-*b*]pyrazine, TNAD,  $C_6H_{10}N_8O_8$ ,  $M = 322.192$  g/mol, the cyclic amine *trans*-1,4,5,8-tetraazadecalin was first prepared from glyoxal and ethylenediamine and then nitrated to TNAD with  $HNO_3$  in acetic acid anhydride [519, 520]. The nitration was carried out in three steps.

1,4,5,8-Tetranitro-1,4,5,8-tetraazadecalin

The thermal stability of *N*-nitroamines possessing two fused five-membered rings is not any better than that of RDX or HMX [521, 522].

### 16.3 Caged Heterocyclic Nitramines

Normally hexanitrohexaazaisowurtzitane, CL-20, the high-density caged heterocyclic nitramine that has received a lot of attention during the past decades, would receive

a chapter with detailed information at least as complete as the chapters for RDX and HMX. However, the primary application of CL-20 is as an explosive and not as a rocket propellant ingredient. Therefore we have not included a more detailed description of CL-20 in this chapter. Hexanitrohexaazaisowurtzitane is a polyazapolycyclic caged nitramine and has a remarkable density, and detonation velocity. The abbreviation CL stems from the U.S. Navy laboratory where it was discovered in 1986: China Lake, CA.

## 17 *N,N*-Dinitramine Compounds

In an effort to synthesize energetic compounds, not only one, but also both hydrogens on the amino nitrogen of alkylamines can be replaced by nitro groups. The resulting compounds are called *N,N*-dinitroalkylamine compounds or *N,N*-dinitramines or *N,N*-dinitramides or *N*-alkyl-*N,N*-dinitroamines. Because they no longer contain an acidic hydrogen like the simple (single) nitramines, they do not form salts. Alkyl-dinitramines play a role in the synthesis of inorganic dinitramide salts (see *Encyclopedia of Oxidizers*, chapter “Dinitramide Oxidizers”).

The C—N bond in alkyl dinitramines is easily split by hydrolysis with strong alkali hydroxide, yielding the corresponding alkali dinitramide salts. The alkyl dinitramines can be isolated as intermediates, purified or can be hydrolyzed without intermediate purification if dinitramide salts are the desired product. In addition to being useful as intermediates in the production of ammonium dinitramide (ADN) or potassium dinitramide (KDN), alkyl dinitramides would make good monopropellants similar to nitroalkanes.

### 17.1 Synthesis of Alkyl Dinitramines

Alkyl *N,N*-dinitramines were already synthesized long before their potential use as intermediates in the production of ADN became known [523]. A classical metathetical reaction for the synthesis of *N,N*-dinitramines would be the reaction of silver dinitramide with an alkyl iodide, precipitating the insoluble silver iodide. Silver dinitramide reacts with alkyl iodides to form *N*-alkyl-*N,N*-dinitroamines [524, 525]:

Methyl iodide does not react with  $\text{KN}(\text{NO}_2)_2$  in acetonitrile at 253 K, but  $\text{AgN}(\text{NO}_2)_2$  reacts with  $\text{CH}_3\text{I}$  within several days to form methyldinitroamine

The reaction with  $\text{C}_2\text{H}_5\text{I}$  gave a mixture of *N*- and *O*-alkylated products.

The synthesis of monoalkyl-*N,N*-dinitramines from isocyanates as a step for preparation of dinitramide salts was already described in *Encyclopedia of Oxidizers*,

chapter “Dinitramide Oxidizers.” Alkyl *N,N*-dinitramines can be obtained by the direct nitration of the corresponding alkyl isocyanates with  $\text{NO}_2\text{BF}_4/\text{HNO}_3$ . If alkali metal dinitramide salts are already available by synthesis via a different route, they can be converted into alkyldinitramines by alkylation methods. For instance, cesium dinitramide can be converted into the alkyldinitramine by reaction with the corresponding alkyl triflates. The product yield was 40%.

Alkylation of dinitramidic acid with diazomethane in ether gave methyl dinitramine in 30% yield

Cubanes with *N,N*-dinitroamino instead of nitro pendants have not yet been synthesized, but their molecular structure and energy potential has already been calculated. The heats of formation, the detonation velocity and detonation pressure of poly-*N,N*-dinitroaminocubanes were calculated by density function theory (DFT) methods [526]. The results showed that all cubane derivatives have positive heats of formation, which increase with increasing number of dinitroamino groups attached to the cube. The detonation performances of polydinitroaminocubanes were estimated by the Kamlet–Jacobs equation, and the results indicated that most cubane derivatives have good detonation performance, better than RDX or HMX.

## 17.2 Properties of Alkyl Dinitramides (Alkyl *N,N*-Dinitramines)

Most alkyl dinitramines are thermally less stable than the nitramines or even the corresponding nitro compounds. They are quite energetic and could be used as rocket propellants if they can be stored at low temperatures. The enthalpies of formation of methyl dinitramine and *n*-butyl dinitramine were determined from the heat of combustion in a calorimeter and the data for ethyl dinitramine and *n*-propyl dinitramine were interpolated from the experimental data (Table 37). The heat of evaporation was measured calorimetrically and used to calculate the enthalpy of formation in the vapor state [20].

## 17.3 Decomposition of Alkyl *N,N*-Dinitramines

Success in the synthesis of the dinitramide salts and the preparation of related alkyldinitramines [527] made it possible to study the thermochemical characteristics and the kinetics of the gas-phase radical thermal decomposition of methyl-dinitramine [528]. It was shown that all alkyldinitramines studied decompose via the radical mechanism with the elimination of the  $\text{NO}_2$  group at the first stage. Therefore,

**Table 37:** Thermochemical properties of alkyldinitramines in the liquid and vapor state at 298 K.

| Compound                                     | $\Delta H_f^{298}(\text{L})$ |             | $\Delta H_{\text{vap}}^{298}$ |          | $\Delta H_f^{298}(\text{G})$ |            | $E_a$    |            |

Data source: [20]

if the data on the enthalpies of formation in the gas phase are available, the enthalpies of formation of radicals of the  $\text{RN}^\bullet\text{—NO}_2$  type and the bond dissociation energies of the nearest environment of the  $\text{NNO}_2$  group can be calculated.

In a study of the thermal decomposition of a series of alkyldinitramines, it was shown that the thermal decomposition of *N,N*-dinitramines is homogeneous and unimolecular in the gas phase [529]. The limiting step of the process is the rupture of the  $\text{N—NO}_2$  bond. The activation parameters of the process imply that the dinitramine group is more reactive than the mononitroamine group in thermal decomposition. The energy of dissociation of the  $\text{N—NO}_2$  bond in dinitramines is  $\sim 42\text{ kJ/mol}$  less than in mononitroamines. Nitrogen dioxide did not influence the kinetics of thermal decomposition of dinitroamines.

The activation energy of thermal decomposition of alkyldinitramines  $124 \pm 12\text{ kJ/mol}$  ( $29.7 \pm 3.0\text{ kcal/mol}$ ) makes it possible to calculate the enthalpies of formation of alkyl nitramine radicals which form as the first step of decomposition and the  $\text{RN}^\bullet\text{—NO}_2$  bond dissociation energy values [20].

## 18 Nitroamides, Nitroimides, and Nitrocarbamates

Nitroamides can be prepared by nitration of amides or imides instead of nitration of amines. The two simplest nitroamides are nitrourea and dinitrourea, which are discussed in *Encyclopedia of Liquid Fuels*, chapter “Amides and Imides” and not here in the chapter on nitramines. Representatives for another type of nitroamides are mononitrobiuret and 1,5-dinitrobiuret. The nitroimide with the most widespread used as a propellant ingredient is nitroguanidine (NQ). Nitroguanidine is a nitramine and should have been discussed here in the chapter “Nitramines” along with other nitramines, but somehow was kept in chapter “Amides and Imides,” with its parent amide, guanidine. The same applies for dinitroguanidine and nitroaminoguanidine.

Cyclic *N*-nitroureas such as 1,4-dinitroglycouril (DINGU) and 1,3,4,6-tetranitroglycouril (TNGU) are also described in this volume’s chapter “Amides and Imides.”

Nitrocarbamates derived from nitrocarbamic acid  $\text{O}_2\text{NNHCOOH}$  have been evaluated as energetic additives. The acid itself is unstable, but its esters are stable. Its nitroalkyl esters are under evaluation as energetic plasticizers because they have a positive oxygen balance. These include 2,2,2-trinitroethyl nitrocarbamate,  $(\text{O}_2\text{N})_3\text{CCH}_2\text{O—CO—NH—NO}_2$  [530, 531]. A variety of energetic compounds combining nitroalkyl groups with nitrocarbamate groups were synthesized [532]. The precursors, polynitro alcohols, were obtained by condensation of the readily available starting material nitromethane with small aliphatic aldehydes formaldehyde and glyoxal. The conversion into carbamates was achieved with the reactive chlorosulfonyl isocyanate and a final nitration yielded the polynitrocarbamates.

# Organometallic Compounds

## 1 Organometallic Compounds

Organometallic compounds contain an organic group, normally an alkyl group, and a light metal that has the potential to increase the heat of combustion of the compound. An organometallic compound is defined as one possessing a direct metal-to-carbon bond. Thus, compounds in which the metal is bonded to the carbon only by oxygen, nitrogen, or sulfur bridges are not included here. Organometallic compounds are not used as the main fuels in rocket engines, but mostly as ignition fluids, due to their pyrophoric properties in air and in the presence of other oxidizers such as LOX. This chapter on organometallic compounds is closely related to the chapter “Alkylboranes” and the chapter “Metals of the Second and Third Row of the Periodic Table of Elements, and their Hydrides” in this set named *Encyclopedia of Liquid Fuels*.

The terms *metalorganic compounds* and *organometallic compounds* have been used interchangeably to denote a class of compounds containing metals or metalloids and organic groups, but organometallic compounds is the preferred term. Also used interchangeably are the terms *metal alkyls*, *alkyl metals*, and *organometals* to describe those compounds. These are compounds obtained through the formation of covalent bonds between a metal (or a metalloid such as silicon) and a carbon atom of an alkyl or aryl group.

The nomenclature of organometallic compounds is not always very consistent, as the name of the metal may be at the beginning or at the end of the word describing the compound, e.g., aluminum triethyl or triethylaluminum. We prefer the latter spelling, and in one word. Organometallic compounds are discussed here in order of the metal's atomic number.

The main applications of some organometallic compounds, such as those of gallium and arsenic, are in the production of semiconductors and photovoltaic cells by doping the silicon matrix with alioelectronic atoms by metal organic chemical vapor deposition (MOCVD). Other organometallic compounds are alkylating agents and are used in organic synthesis to introduce alkyl groups into other compounds. Triethylaluminum or trimethylaluminum complexes with titanium chloride or magnesium chloride are Ziegler–Natta catalysts that are essential for the production of low-density polyethylene and polypropylene and are used for this purpose in industrial quantities.

At one time, tetraethyllead was added to gasoline to improve its octane rating. Tetraethyllead is no longer used for this purpose in land-based vehicles in developed countries, but the lead pollution caused by its decades-long use lingers on our highways and in some waterways. Tetraethyllead is still used as an additive in some grades of aviation gasoline, and for automobiles in some developing countries.

One of the first organometallic compounds available was diethylzinc. It is pyrophoric in air and has been used as an ignition fluid for rocket engines. Many

organometallic compounds have to be handled with extreme care to avoid exposure to oxygen (air) or moisture [1].

Many periodicals and serial publications are exclusively devoted to organometallic compounds: *Organometallic Chemistry*, *Journal of Organometallic Chemistry*, *Organometallic Chemistry in Industry*, *Organometallic Chemistry Reviews*, *Advances in Organometallic Chemistry*, *Applied Organometallic Chemistry*, *Physical Organometallic Chemistry*, and several more.

## 2 Alkylberyllium Compounds

All beryllium compounds are very toxic, and in the case of alkylberyllium compounds, this problem is aggravated by the high volatility of these compounds (compared to beryllium metal or beryllium hydride). If they ignite in air, the resulting beryllium oxide smoke is highly hazardous. Alkylberyllium compounds have only been used as intermediates in the synthesis of other beryllium compounds, mainly beryllium hydride, and they seem to have no other applications. The physical properties of alkylberyllium compounds are summarized in Table 1.

Substitution of hydrogens with methyl groups causes a progressive decrease in the thermal stability of the compound in the order  $\text{Me}_2\text{Be} > (\text{MeCH}_2)_2\text{Be} > (\text{Me}_2\text{CH})_2\text{Be} > (\text{Me}_3\text{C})_2\text{Be}$ . Di-*tert*-butylberyllium,  $(\text{Me}_3\text{C})_2\text{Be}$ , also called beryllium, bis(1,1-dimethylethyl)-, was prepared by reacting  $\text{BeCl}_2 \cdot \text{Et}_2\text{O}$  for 2 h with  $\text{Me}_3\text{CMgCl}$  under nitrogen, and most (not all) of the ether was removed *in vacuo* at room temperature [5]. Vac-

**Table 1:** Physical properties of alkylberyllium compounds.

| Compound                        | CAS RN     | Property             | SI units               | Other units         | References |
|---------------------------------|------------|----------------------|------------------------|---------------------|------------|
| Dimethylberyllium               | 506-63-8   | Melting point        | 473 K (dec.)           | 200 °C (dec.)       | —          |
|                                 |            | Sublimation point    | 473 K (dec.)           | 200 °C (dec.)       | [2]        |
|                                 |            | Vapor pressure       | 80 Pa at 373 K         | 0.6 mm Hg at 100 °C | —          |
|                                 |            | Heat of sublimation  | 98.3 kJ/mol            | 23.5 kcal/mol       | —          |
| Diethylberyllium                | 542-63-2   | Freezing point       | 260–262 K              | –13 to –11 °C       | [2]        |
|                                 |            | Boiling point        | 383 K at 2 kPa         | 110 °C at 15 mm Hg  | [2]        |
|                                 |            |                      | 467 K                  | 194                 | —          |
|                                 |            | Vapor pressure       | 2 kPa at 383 K         | 15 mm Hg at 110 °C  | —          |
| Diisopropylberyllium            | 15721-33-2 | Heat of vaporization | 41.8 kJ/mol            | 10.0 kcal/mol       | —          |
|                                 |            | Freezing point       | 263.6 K                | –9.5 °C             | [3]        |
|                                 |            | Boiling point        | 553 K                  | 280 °C              | —          |
|                                 |            | Vapor pressure       | 23 Pa at 293 K         | 0.17 mm Hg at 20 °C | —          |
| Di- <i>tert</i> -butylberyllium | 7390-83-2  | Freezing point       | 257 K                  | –16 °C              | —          |
|                                 |            | Density              | 0.57 g/cm <sup>3</sup> | —                   | —          |

Additional data from [4]

uum distillation of the residue yielded di-*tert*-butylberyllium, which was non-volatile at room temperature and unaffected by exposure to air for short periods of time. Di-*tert*-butylberyllium,  $(\text{Me}_3\text{C})_2\text{Be}$  was pyrolyzed to give  $\text{BeH}_2$ . Hydrolysis of the crude di-*tert*-butylberyllium with dilute aqueous HCl gave some  $\text{Et}_2\text{O}$  and isobutane, corresponding to an etherate containing 55.4 mol-% di-*tert*-butylberyllium. Pyrolysis of di-*tert*-butylberyllium at 483 K (210 °C) gave a white solid, isobutylene, and a little  $\text{Et}_2\text{O}$ . Hydrolysis of the solid residue with acid indicated that it consisted of 96.3 mol-%  $\text{BeH}_2$ . The reaction of  $\text{BeH}_2$  with  $\text{B}_2\text{H}_6$  at 428 K (155 °C) formed some  $\text{BeB}_2\text{H}_5$ .

Beryllium hydride can be prepared by the pyrolysis of both pure di-*tert*-butylberyllium and its etherate [6]. Pure di-*tert*-butylberyllium is a clear, colorless, mobile liquid with a density of  $0.65 \text{ g/cm}^3$  and a freezing point of 257 K (−16 °C). When freshly prepared, it had a vapor pressure of about 4.7 kPa at 298 K (35 mm Hg at 25 °C). On standing, it undergoes slow decomposition at room temperature with the evolution of isobutene. Di-*tert*-butylberyllium etherate can be prepared from *tert*-butyl-magnesium chloride and  $\text{BeCl}_2$  to give ~50 mol-% of the interim product. Treatment of di-*tert*-butylberyllium etherate with anhydrous  $\text{BeCl}_2$  in  $\text{Et}_2\text{O}$  in an inert nitrogen atmosphere overnight gives a 40% yield of ether-free di-*tert*-butylberyllium. This is a useful intermediate in the synthesis of beryllium hydride.

Thermal decomposition of dimethylberyllium starts at 475 K (202 °C), initially leads to  $\text{Be}(\text{CH}_2)_n$ , and later results [7] in  $\text{Be}_2\text{C}$ , not  $\text{BeH}_2$ . The thermal decomposition of alkylberyllium compounds (other than dimethylberyllium) is of interest for the preparation of beryllium hydride, once actively investigated as a rocket fuel. The potential energy surfaces of unimolecular dissociation reactions for diethylberyllium and di-*tert*-butylberyllium were investigated by computational chemistry [8]. Possible reaction pathways through either the radicals or transition states of the molecules were considered. From a study of the energetics, the transition state pathways arising from concerted molecule fragment eliminations were indicated to be the main dissociation pathways for both molecules. Dimethylberyllium and methylberyllium form a complex salt,  $\text{Li}_2[\text{Be}(\text{CH}_3)_4]$ , with a tetrahedral grouping of methyl groups around the beryllium atom.

### 3 Alkylboron Compounds

Alkylboron compounds are discussed in the chapter “Alkylboranes” in this set, the *Encyclopedia of Liquid Fuels*.

## 4 Alkylmagnesium Compounds

The lower alkylmagnesium compounds dimethylmagnesium,  $\text{Mg}(\text{CH}_3)_2$ , CAS RN [2999-74-8], and diethylmagnesium,  $\text{Mg}(\text{C}_2\text{H}_5)_2$ , CAS RN [557-18-6], are pyrophoric in air and are of interest as ignition fluids in rocket engines and ramjets. The lower normal dialkylmagnesium compounds ( $\text{C}_1\text{--C}_4$ ) and one branched compound (diisopropylmagnesium) have been found to be solids at room temperature and essentially insoluble in both aromatic and aliphatic hydrocarbons. Dimethylmagnesium is a solid that forms polymeric chains where several magnesium atoms are linked via methyl bridges and hydrogen bonding, thus reducing the volatility and melting point of this compound. Diethylmagnesium is a liquid that freezes at 273 K (0 °C). Diethylmagnesium is in equilibrium with its dimer in THF solution.

### 4.1 Preparation of Alkylmagnesium Compounds

The most frequently used organomagnesium compounds are the Grignard reagents  $\text{RMgX}$ , where R is an alkyl or aryl group and X is a halogen, most often bromide but also iodide or chloride. Grignard reagents are widely used in organic synthesis as alkylating agents. They are usually only used in solution (ether solution) and rarely prepared in the pure state. They serve as the precursors for halogen-free magnesium alkyls that can be used as ignition fluids in rocket engines.

Dimethylmagnesium or diethylmagnesium can be prepared by adding at least one equivalent of dioxane to a solution of the alkylmagnesium halide [9]:

The complex of magnesium dihalide and dioxane precipitates as a solid, driving the equilibrium to the right to give the dialkylmagnesium compound, which remains in solution. The complex of magnesium dihalide and dioxane is more stable than the complex of diethylmagnesium and dioxane [10]. In order to remove the dioxane from the diethylmagnesium–dioxane complex, the residue has to be heated at 393 K (120 °C) under a reduced pressure of 1–2 mm Hg for 30 h. The white crystals of diethylmagnesium can then be powdered under a nitrogen atmosphere.

A historical method for the preparation of alkylmagnesium compounds is the reaction of magnesium metal with alkylmercury compounds, but this method is dangerous due to the volatility and toxicity of the alkylmercury compounds used as reagents. It operates at high temperatures, which precludes the synthesis of alkylmagnesium compounds with low thermal stability.

A commercial method for the production of diethylmagnesium is the reaction of magnesium metal with hydrogen and ethylene at 373 K (100 °C) at very high pressures, similar to the synthesis of triethylaluminum.

Higher ( $C_3$ – $C_5$ ) dialkylmagnesium compounds have been prepared by **(1)** direct reaction of magnesium metal with alkyl halides in hydrocarbon media containing a limited amount of a Lewis base such as dimethyl ether, **(2)** reaction of Grignard reagents with stoichiometric amounts of lithium alkyls, and **(3)** reaction of activated anhydrous magnesium chloride with lithium alkyls in hydrocarbon media [11]. Some dialkylmagnesium compounds prepared in media containing ethers can be desolvated from the Lewis base by continuous co-distillation with hydrocarbon solvents.

## 4.2 Physical Properties of Alkylmagnesium Compounds

The physical properties reported for alkylmagnesium compounds by different investigators often vary because of unrecognized etherate contents of the samples. It is difficult to remove the last traces of ether from the compounds. Some compounds decompose before all dioxane can be removed. Di-*n*-butylmagnesium is an infusible solid at room temperature but di-*sec*-butylmagnesium is a liquid. Physical properties of alkylmagnesium compounds are summarized in Table 2.

**Table 2:** Physical properties of alkylmagnesium compounds.

| Compound          | Property       | SI units                | Other units   | References |
|-------------------|----------------|-------------------------|---------------|------------|
| Dimethylmagnesium | Molecular mass | 54.38 g/mol             | 18.389 mol/kg | —          |
|                   | Density        | 0.96 g/cm <sup>3</sup>  | —             | —          |
| Diethylmagnesium  | Molecular mass | 82.43 g/mol             | 12.132 mol/kg | —          |
|                   | Freezing point | 273 K                   | 0 °C          | [10]       |
|                   | Density (XRD)  | 0.964 g/cm <sup>3</sup> | —             | [12]       |

The crystal structure of solid diethylmagnesium determined from XRD powder data is a primitive tetragonal lattice ( $a = 7.294 \text{ \AA}$ ,  $c = 5.338 \text{ \AA}$ ;  $V = 284 \text{ \AA}^3$ ,  $Z = 2$ ,  $\rho = 0.964 \text{ g/cm}^3$ ) with polymeric chains parallel to the  $c$  plane [12].

## 4.3 Chemical Properties of Alkylmagnesium Compounds

Alkylmagnesium compounds are pyrophoric in air and hydrolyze rapidly with water.

Some alkylmagnesium compounds decompose before all dioxane can be removed. Di-*tert*-butylmagnesium undergoes thermal decomposition when desolvation is attempted, even at temperatures well below 373 K (100 °C). The thermal

decomposition of diethylmagnesium leads to magnesium hydride. It starts at 448 K (175 °C) but goes to completion only at temperatures where  $\text{MgH}_2$  starts to decompose.

Thermographic examination of diethylmagnesium gave two endotherms: 563 and 643 K (290 and 370 °C);  $\text{Et}_2\text{Mg}$  first decomposes to  $\text{MgH}_2$  and  $\text{C}_2\text{H}_4$  and further decomposition yields Mg and  $\text{H}_2$ . The pyrolysis of  $(\text{C}_2\text{H}_5)_2\text{Mg}$  under vacuum yielded  $\text{MgH}_2$ , which decomposed endothermically on further heating at 663 K (390 °C), similar to other samples of  $\text{MgH}_2$  that were synthesized by other means [10]. No change in  $\text{Et}_2\text{Mg}$  was noted in the IR spectra at temperatures up to 483 K (210 °C).

#### 4.4 Applications of Alkylmagnesium Compounds

Because diethylmagnesium and most other alkylmagnesium compounds are pyrophoric in air, they have been proposed as ignition fluids for hydrocarbons in air-breathing jet or ramjet engines. Some alkylmagnesium compounds are soluble in jet fuels and make them combustible and re-ignitable in thin air at higher altitudes and less susceptible to flameouts.

Mixtures of dimethylmagnesium, diethylmagnesium, di-*n*-propylmagnesium and diisooctylmagnesium are soluble in aliphatic, cycloaliphatic, and aromatic hydrocarbon solvents without the aid of solubilizing agents [13, 14]. Some diorganomagnesium compounds with straight chain lower alkyl groups of up to four carbon atoms are insoluble by themselves in hydrocarbon solvents and thus require solubilizing agents, which will form a soluble complex. Examples of such solubilizing agents are alkyl-lithium compounds, dialkyl zinc compounds, alkali metal hydrides, and organoaluminum compounds [15]. Solvation involves the use of an ether or another organic Lewis base molecule that associates directly with the magnesium atom, thus yielding a hydrocarbon-soluble complex, but solvation reduces the reactivity and ignition speed. Alkylmagnesium bromides are widely used as Grignard reagents in organic synthetic chemistry.

### 5 Alkylaluminum Compounds

Alkylaluminum compounds, organoaluminum compounds, alkylalanes, are pyrophoric and ignite spontaneously in air or in contact with liquid oxygen and other oxidizers. The spontaneous reactivity and the high heat of combustion and high emissivity of hot aluminum oxide particles makes them valuable ignition fluids. Alkylaluminum compounds have also been proposed for the ignition of solid propellants [16].

Trimethylaluminum and triethylaluminum ignite spontaneously in air or in contact with LOX [17, 18]. In the series trimethylaluminum, triethylaluminum, tri-

*n*-propylaluminum, triisopropylaluminum, all except the last one are dimeric at room temperature [19]. There are numerous summary publications on organoaluminum compounds [20–24].

The carbon–aluminum bonds in trialkylaluminum compounds are dynamic, rapidly exchanging intermolecularly in mixtures of two compounds, even under ordinary conditions, and the exchange rate increases with temperature.

## 5.1 Trimethylaluminum

Trimethylaluminum, trimethylalane,  $\text{Al}(\text{CH}_3)_3$ , CAS RN [75-24-1], TMA, exists almost completely as the dimer in the liquid state. If trimethylaluminum existed only as a monomer, its boiling point would be 281 K (8 °C), and if it existed only as the dimer, its boiling point would be 405 K (131.9 °C) [25]. In practice, it boils at 342–345 K at 13.3 kPa (69–72 °C at 100 mm Hg) and melts at 288 K (15 °C). The results indicate that the extent of dissociation of liquid TMA is 0.0047% at 293 K (20 °C), 0.053% at 343 K (70 °C), and 0.32% at 393 K (120 °C).

### 5.1.1 Preparation of Trimethylaluminum

Trimethylaluminum can be prepared by refluxing a mixture of methyl iodide and aluminum powder under an atmosphere of nitrogen or argon. The mixture is refluxed at atmospheric pressure for at least 12 h or until all methyl iodide has reacted. The pressure is then reduced to 13 kPa (100 mm Hg) and the temperature is raised. Methyl iodide boils at 315.5 K (42.4 °C) and trimethylaluminum boils at 342–345 K at 13.3 kPa (69–72 °C at 100 mm Hg), so they can be separated on a long distillation column with 10–20 theoretical plates.

A less direct but more economical process for preparation of trimethylaluminum is by way of dimethylaluminum sesquichloride. Alkylaluminum sesquihalide products from reactions of aluminum with alkyl halides can be converted to dialkylaluminum halide or trialkylaluminum by treatment with active metals such as sodium or magnesium. For example, dimethylaluminum chloride or trimethylaluminum can be produced from methylaluminum sesquichloride by sodium reduction:

A magnesium–aluminum alloy can provide a reducing function concurrently with the reaction between aluminum and the alkyl halide:

The sesquichloride reduction process is a very economical route for the production of trimethylaluminum.

### 5.1.2 Physical Properties of Trimethylaluminum

Physical properties of trimethylaluminum are summarized in Table 3.

**Table 3:** Physical properties of trimethylaluminum.

| Property       | SI units                                  | Other units           | References |
|----------------|-------------------------------------------|-----------------------|------------|
| Molecular mass | 72.09 g/mol                               | 13.87 mol/kg          | —          |
| Freezing point | 288 K                                     | 15 °C                 | [19]       |
| Boiling point  | 342–345 K at 13.3 kPa                     | 69–72 °C at 100 mm Hg | [18]       |
|                | 400 K at 101.3 kPa                        | 127 °C at 1 atm       | [23]       |
| Density        | 0.752 g/cm <sup>3</sup> at 293 K = 20 °C  | —                     | [19]       |
|                | 0.7478 g/cm <sup>3</sup> at 298 K = 25 °C | —                     | [23]       |

#### 5.1.2.1 Molecular Structure of Trimethylaluminum

Trimethylaluminum exists almost completely as the dimer. The dimerization is less pronounced with triethylaluminum. The existence of the trimethylaluminum dimer has aroused considerable interest and some dispute among chemists specializing in molecular structure theory [26]. The dispute about the monomer–dimer equilibrium of trimethylaluminum is reflected in the detail in which they have been studied, yet there is considerable apparent disagreement in the measured thermodynamic constants of the equilibrium [27]. NMR spectroscopy has been reasonably successful in investigating the details of the monomer–dimer equilibrium of trimethylaluminum. The spectrum showed a sharp singlet at room temperature with a chemical shift  $\tau$  of 10.3, but as the temperature was reduced the line broadened, and by 213 K (–60 °C) it had split into two lines at 9.50 and 10.65. At room temperature, all the methyl groups are equivalent at the time scale of NMR spectroscopy ( $10^{-3}$  s), and only at a lower temperature can a clear distinction be made between the terminal and bridge groups. The average lifetime of each configuration was calculated and used to determine the unimolecular rate constant for the rate-determining step in alkyl group exchange reactions. An Arrhenius plot of the rate constants over the temperature range 263–213 K (–10 to –60 °C) gave an activation energy of 65.3 kJ/mol (15.6 kcal/mol) for this process. The overall activation energy,  $E_{\text{act}} = 59.0$  kJ/mol = 14.1 kcal/mol, was considered to be

consistent with the value of 64.4 kJ/mol (15.4 kcal/mol) for the dimer. NMR studies have also been made of higher alkylaluminum compounds, and these reached the same general conclusions about rapid alkyl group interchange at room temperature. Electron diffraction determinations were in satisfactory agreement with an ethane structure. However, this structure was at one time considered unlikely for many reasons: **(1)** it differs from the bridge structures of the related aluminum halides  $\text{Al}_2\text{X}_6$ , aluminum dimethyl-halides  $\text{Al}_2\text{Me}_4\text{X}_2$ , and boron and (probably) aluminum hydrides; **(2)** it could not be accounted for by any valence theory that existed at that time, as no forces were available to join the two  $\text{AlMe}_3$  molecules; **(3)** it requires a shorter interatomic distance (about 2.20 Å) between the equally charged Al atoms than that of a covalent Al—Al linkage (2.48 Å); **(4)** the instability (non-existence) of a similar molecule, the boron trimethyl dimer, could not be explained.

The degree of dissociation and the equilibrium as a function of temperature can be determined by measuring the heat of dilution [28]. The enthalpy of dissociation  $\Delta H^\circ_{\text{d}}$  of liquid trimethylaluminum dimer is  $81.2 \pm 1.2$  kJ/mol of dimer ( $19.40 \pm 0.30$  kcal/mol of dimer), and the enthalpy of dissociation  $\Delta H^\circ_{\text{d}}$  of liquid triethylaluminum dimer is 70.8 kJ/mol of dimer (16.93 kcal/mol of dimer) [25]. The  $\Delta H^\circ_{\text{d}}$  of gaseous triethylaluminum was derived as  $76.0 \pm 1.2$  kJ/mol of dimer ( $18.17 \pm 0.30$  kcal/mol of dimer). The heat of dissociation of the dimer depends on the type of solvent used for the experiment [29]. Similar studies were performed on the dimerization of triisobutylaluminum [30]. Triisobutylaluminum, a bulkier molecule, is only 39.4% associated at 283 K (10 °C), and only 16.4% associated at 313 K (40 °C).

A gas-phase electron diffraction investigation of the molecular structures of trimethylaluminum monomer and dimer showed that gaseous trimethylaluminum consists of monomeric and dimeric species in a pressure- and temperature-dependent equilibrium [31]. The equilibrium constant for the reaction is given by

$$\log = K_{\text{D}}(-4457/T) + 9.44$$

Consequently, trimethylaluminum gas at 333 K and 4 kPa (60 °C and 30 mm Hg) is more than 97% dimers, while the gas at 488 K (215 °C) and the same pressure is more than 96% monomers.

The trimethylaluminum dimer has a bridge structure with a skeletal symmetry of  $D_{2h}$  within the accuracy of a structural determination of single crystals by XRD [32]. The atomic distance Al—C in each bridge bond is 2.24 Å, whereas the Al—C bonds for the exterior methyl groups are each 1.99 Å long. The bridge angle  $\angle \text{Al—C—Al}$  is 70°, and the exterior angle  $\angle \text{C—Al—C}$  is 124°. It was shown that a simple model provides the right order of magnitude for the heat of dimerization, and it indicated the relative importance of the Al—C and Al—Al bonds. It was suggested that the sharp bridge angle required for good bridge bonding leads to metal–metal repulsion, which should increase as the size of the metal increases. This probably plays a role in the instability and molecular structure of polymers of the heavier trialkylmetal compounds.

### 5.1.2.2 Thermodynamic Properties of Trimethylaluminum

The heat of reaction of liquid trimethylaluminum with acetic acid in toluene to give  $\text{Al}(\text{OCOCH}_3)_3$  and  $\text{CH}_4$  was measured in a rotating bomb calorimeter [33, 34]. Subsequently, the heat of reaction of  $\text{Al}(\text{OCOCH}_3)_3$  with aqueous 4.36M HCl was measured. These data were combined and used to calculate the enthalpy of formation of liquid trimethylaluminum,  $\Delta H_f^\circ = -151.0 \pm 6.7 \text{ kJ/mol} = -36.1 \pm 1.6 \text{ kcal/mol}$ , and that of crystalline  $\text{Al}(\text{OCOCH}_3)_3$ ,  $\Delta H_f^\circ = -1890 \pm 3 \text{ kJ/mol} = -451.8 \pm 0.8 \text{ kcal/mol}$ . The mean bond dissociation energy was calculated as  $D(\text{Al}-\text{Me}) = 270 \pm 8 \text{ kJ/mol} = 64.5 \pm 2.0 \text{ kcal/mol}$ . Other data for the enthalpy of formation of trimethylaluminum listed in the literature are  $-144.4 \pm 11.1$ ,  $-120.1 \pm 10.0 \text{ kJ/mol}$ , and  $-151.9 \text{ kJ/mol}$ , indicating wide scatter [35].

### 5.1.3 Chemical Properties of Trimethylaluminum

#### 5.1.3.1 Oxidation of Trimethylaluminum

Trimethylaluminum reacts rapidly with diluted oxygen at 298 K (25 °C) to give a non-peroxidic solid and methane [36]. This reaction can induce selective higher hydrocarbon oxidation. The lower flammability limit of trialkylaluminum is raised by dilution with hydrocarbons. Methane and hydrogen were the only gaseous products found during the slow oxidation of trimethylaluminum. The marked dependence of the ignition limit on the surface: volume ratio is an indication of the radical chain nature of the ignition. Using the observed temperature variation, a plot of  $\log(AT)$  against the reciprocal absolute temperature, rough values of the activation energies of two of the reactions in the mechanism could be obtained. Studies of the spontaneous ignition of mixtures of trimethylaluminum and oxygen have shown that the ignition boundary is defined by the expression

$$\frac{1}{p_{\text{Me}_6\text{Al}_2}} = A - \frac{B}{p_{\text{O}_2}}$$

where  $p_{\text{Al}_2\text{Me}_6}$  and  $p_{\text{O}_2}$  are the partial pressures of the reactants. The values of A and B are only slightly affected by temperature and by added inert gases. The main products formed during ignition are hydrogen, carbon monoxide, methane, acetylene, and a complex, gray, aluminum-containing solid. The kinetic and analytical findings can be accounted for in terms of an isothermal free-radical chain mechanism. This mechanism correctly predicted the effects of reactant pressures, temperature, and helium but failed to account quantitatively for the influence of the surface: volume ratio. As the ignition limit is approached from the slow combustion region, the branching reactions

appear to become important and lead to ignition [37]. Cinephotography of the gases in the reaction vessel showed that the delay preceding ignition is less than 0.1 s and that propagation of the explosion throughout the mixture is complete in less than 0.015 s. Experiments were performed in a Pyrex vessel at 298 K (25 °C) with a volume of 143 cm<sup>3</sup> and a surface : volume ratio of 1.18 cm<sup>-1</sup>. Figure 1 shows that the partial pressures of the two reactants at the ignition boundary are related by an expression of the type shown above.

**Figure 1:** Ignition boundary for trimethylaluminum/oxygen mixtures (Republished and modified from [37], with the permission of ©1966 The Royal Society of Chemistry; permission conveyed through Copyright Clearance Center Inc.)

The variation in the limiting ignition pressure with the mol fraction of oxygen showed a minimum at an oxygen mol fraction of 0.63. The solid products of the combustion of trimethylaluminum do not affect the rate or course of subsequent combustion, which appears to involve the homogeneous decomposition of a transient peroxide [38]. This latter reaction produces free radicals capable of inducing the oxidation of hydrocarbons at ambient temperatures. In the combustion of certain metal alkyls, the rate-determining steps are heterogeneous. The relative importance of homogeneous and heterogeneous rate-determining processes appears to be a function of the electron deficiency of the metal alkyl.

### 5.1.3.2 Reactions with Lewis Acids

Trimethylaluminum forms an adduct with ammonia that may also be used as an ingredient in rocket propellants:

The adduct can be used for the deposition of aluminum nitride films in the construction of integrated circuits by MOCVD. Aluminum nitride is an electric insulator but has good thermal conductivity.

Solution calorimetric techniques in hexane have been used to determine the enthalpies of formation of a number of trimethylaluminum Lewis adducts with phosphorus, nitrogen, and oxygen electron donors [39]. The enthalpies of the exothermic reactions (in kJ/mol, followed by kcal/mol in parentheses) were:  $\text{N}(\text{CH}_3)_3$   $-125.3 \pm 0.8$  ( $-29.96 \pm 0.19$ );  $\text{HN}(\text{CH}_3)_2$   $-129.0 \pm 1.1$  ( $-30.84 \pm 0.26$ );  $\text{H}_2\text{NCH}_3$   $-125.6 \pm 1.3$  ( $-30.02 \pm 0.31$ );  $\text{NH}_3$   $-115.3 \pm 1.0$  ( $-27.55 \pm 0.25$ ). There does not appear to be a clear trend in the heat of reaction with a decreasing number of methyl groups in the amine. For the trimethylaluminum/trimethylamine and trimethylaluminum/dimethyl ether systems, appropriate vapor-phase data were used with the calorimetric data to calculate the gas-phase enthalpy. The gas-phase enthalpy of formation of  $(\text{CH}_3)_3\text{Al} \cdot \text{N}(\text{CH}_3)_3(\text{G})$  was  $-135.1 \pm 1.2$  kJ/mol ( $-32.29 \pm 0.29$  kcal/mol).

Partial decomposition of  $(\text{CH}_3)_3\text{Al} \cdot \text{NH}_3$  leads to a cyclic  $[(\text{CH}_3)_2\text{Al}-\text{NH}_2]_3$  trimer along with the release of methane. The thermodynamics, kinetics, and mechanism of the reactions

in homogeneous solution were investigated by solution calorimetry, DSC, and  $^1\text{H}$  NMR rate measurements [40]. The enthalpy for complex formation from  $\text{NH}_3$  and monomeric  $(\text{CH}_3)_3\text{Al}$  in benzene was  $-93$  kJ/mol. The observed  $\Delta H$  for methane loss from the complex was  $-82.2$  kJ/mol.

Adducts of trimethylaluminum may be formed not only as a Lewis adduct by electron transfer, but also through hydrogen bond formation with additional ammonia molecules [41]. The second product is the result of the hydrogen bonding of a second  $\text{NH}_3$  molecule to the  $(\text{CH}_3)_3\text{Al} : \text{NH}_3$  adduct, and can be written as  $(\text{CH}_3)_3\text{Al} : \text{NH}_3 \cdots \text{NH}_3$ . The binding energy of this hydrogen-bonded adduct was calculated to be  $112$  kJ/mol ( $26.8$  kcal/mol).

### 5.1.3.3 Thermal Decomposition of Trimethylaluminum

The thermal decomposition of gaseous trimethylaluminum is of interest for chemical vapor deposition (CVD) of metallic aluminum thin films, but not so much for the use of trimethylaluminum as an ignition fluid in rockets. The thermal decomposition of gaseous trimethylaluminum in the absence of hydrogen was nearly 94% homogeneous and of kinetic order  $3/2$  over the initial pressure range from  $1.3$  to  $11.3$  kPa ( $10$ – $85$  mm Hg), as measured at room temperature prior to heating the sample [42]. The reaction products consisted mostly of methane and to a lesser extent ethane, ethylene, hydrogen, and a solid deposit on the walls of the reaction vessel. A reaction mechanism involving free methyl radicals was proposed. The apparent energy of activation calculated on this basis was estimated to be  $188$  kJ/mol ( $45$  kcal/mol), in agreement

with experimentally determined data. The high ratio of methane produced to alkyl decomposed suggested that trimethylaluminum in the vapor state at room temperature must consist of at least tetrameric molecular complexes. In the presence of hydrogen, both the decomposition rate and the energy of activation were reduced as compared to the decomposition of the pure alkyl, a puzzling effect for which no satisfactory explanation could be offered. Photochemically, the addition of hydrogen seemed to have little effect on the overall decomposition, but it enhanced the relative amount of methane slightly.

The pyrolysis of trimethylaluminum results in the splitting of methane with intermediates in the form of methylene and methine compounds, all ending up as aluminum carbide [43]. A vapor-phase mechanism for the decomposition of trimethylaluminum (TMA) used in an Al CVD was investigated by IR spectrometry [44]. In pyrolysis, the annihilation of TMA was a first-order reaction and  $\cdot\text{CH}_3$  free radicals were generated. The activation energy of the annihilation was about 6.4 kJ/mol (0.4 eV). The generation mechanism of  $\text{CH}_4$  from the intermediates was investigated quantitatively. It was suggested that carbon contamination can be reduced by using an  $\text{H}_2$  carrier gas, since the  $\cdot\text{CH}_3$  radical that causes such contamination is changed into  $\text{CH}_4$  by hydrogenation. In photolysis, the annihilation of TMA was a first-order reaction and  $\text{C}_2\text{H}_6$  was generated by the recombination of two  $\text{CH}_3$  groups. A reduction in carbon contamination was due to the generation of  $\text{C}_2\text{H}_6$ .

## 5.2 Triethylaluminum

Triethylaluminum, also known as triethylalane, aluminum triethyl,  $(\text{C}_2\text{H}_5)_3\text{Al}$ , CAS RN [97-93-8], TEA,  $\text{AlEt}_3$ , has been used for a long time as a hypergolic slug for the ignition of LOX/kerosene engines such as the engines in the SATURN-IC or SATURN-V first stage or LOX/ $\text{LH}_2$  engines for static rocket engine development tests [45]. Triethylaluminum in mixture with triethylborane is currently used as an ignition fluid in LOX/RP-1 engines (FALCON-9, FALCON Heavy). The name of the mixture is often abbreviated to TEA/TEB.

### 5.2.1 Production of Triethylaluminum

Historically, triethylaluminum has been made in small quantities by the reaction of diethylmercury with aluminum metal in a closed bomb heated at 383 K for 30 h:

The same method can be used for preparation of tri-*n*-propylaluminum.

An alternate process for preparation of triethylaluminum is to use diethylaluminum sesquichloride. Alkylaluminum sesquihalide products from aluminum reactions with alkyl halides can be converted to the dialkylaluminum halide or

trialkylaluminum by treatment with active metals such as sodium or magnesium. For example, diethylaluminum chloride or triethylaluminum can be produced from ethylaluminum sesquichloride by sodium reduction:

A magnesium-aluminum alloy can provide the reduction simultaneously with the reaction between aluminum and the alkyl halide:

The production of triethylaluminum in industrial quantities is now achieved by the high-pressure reaction of aluminum metal powder, ethylene, and hydrogen [46, 47]. This reaction is also called hydroalumination of olefins. Diethylaluminum hydride is an intermediate product in this process. It can be converted to triethylaluminum in a secondary treatment with ethylene.

Other than with ethylene, the high-pressure synthesis of trialkylaluminums can be done with higher  $\alpha$ -alkenes. The preparation of trialkylaluminums or dialkylaluminum hydrides in which the alkyl radicals are primary alkyl radicals from metallic aluminum, hydrogen, and olefins is well known. However, it has been repeatedly stressed in the literature that the reaction operates only with  $\alpha$ -olefins, and that it does not work with olefins in which the double bond is in a position other than the terminal position. One of the articles of interest in this respect is [48].

There are two variants of the previously described synthesis of trialkylaluminum and dialkylaluminum hydrides from aluminum metal, hydrogen, and alkenes: **(1)** a one-step synthesis where all three reactants are present at the same time in the reactor, which is favorably applicable to triisobutylaluminum [49], and **(2)** a two-step process in which three mols of dialkylaluminum hydride are formed from two mols of trialkylaluminum in the absence of any alkene:

and the product is then reacted with more alkene in the second step:

The latter method works very well for triethylaluminum [46, 47, 50–52].

### 5.2.2 Physical Properties of Triethylaluminum

Physical properties of triethylaluminum are summarized in Table 4.

**Table 4:** Physical properties of triethylaluminum.

|                                | SI units                               | Other units                              | References    |
|--------------------------------|----------------------------------------|------------------------------------------|---------------|
| Molecular mass                 | 114.17 g/mol                           | 8.7589 mol/kg                            |               |

|                                | 0.8324 g/cm <sup>3</sup> at 298 K      | —                                        | [23]          |
| Specific heat                  | 2.09 J g <sup>−1</sup> K <sup>−1</sup> | 0.5 cal g <sup>−1</sup> °C <sup>−1</sup> | —             |
| Standard enthalpy of formation | −146 kJ/mol                            | −35 kcal/mol                             | —             |
|                                | −152.7 ± 21 kJ/mol                     | −36.5 ± 5 kcal/mol                       | [33, 34]      |
| Heat of vaporization           | 54.4 kJ/mol                            | 13 kcal/mol                              | —             |
| Refractive index               | 1.480 at 589.3 nm and 6.5 °C           | —                                        | CAS SciFinder |

The boiling point of triethylaluminum at sea-level pressure was reported as 463–468 K (190–195 °C), but one must anticipate partial decomposition at that temperature. It is better to distill triethylaluminum under vacuum, where it will boil at 321–329 K at 0.13 Pa (48–56 °C at 0.001 mm Hg), 348–353 K at 0.3 kPa (75–80 °C at 2.5 mm Hg), or 401–403 K at 6.7 kPa (128–130 °C at 50 mm Hg).

#### 5.2.2.1 Vapor Pressure of Triethylaluminum

At room temperature, triethylaluminum exists partially in the dimeric form. With increasing temperature, the dimer dissociates and forms the monomer as a vapor. Vapor pressure and vapor density measurements thus reflect both a physical and a chemical process.

Vapor pressure measurements from different sources are summarized in Table 5. This table contains the constants A and B, which can be used to calculate the vapor pressure as a function of temperature by the equation

$$\log P = A - \frac{B}{T}$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. Some of the heat of dissociation is included in the observed heat of vaporization. See also [53, 54].

**Table 5:** Vapor pressure and heat of vaporization of triethylaluminum.

| A      | B      | $\Delta H_{\text{vap}}$ |            | Trouton constant                      | Temperature range |         | References |

### 5.2.2.2 Molecular Structure of Triethylaluminum

At room temperature, triethylaluminum exists partially in the dimeric form. With increasing temperature, the dimer dissociates and forms the monomer as a vapor. The alkyl bridges holding the dimer together are considerably weaker than hydride bridges. Dimeric trialkylaluminum compounds are in equilibrium with their monomers. The molecular structure of triethylaluminum is illustrated in Figure 2.

**Figure 2:** Molecular structure of triethylaluminum dimer.

The heat of dissociation of triethylaluminum dimer in a solution of *n*-hexadecane was estimated as 70.7 ± 0.8 kJ/mol dimer (16.9 ± 0.2 kcal/mol dimer) [28]. Unfortunately, the experimental conditions were such that there may have been a contribution from the heat of vaporization of the triethylaluminum (16.5 kcal/mol of vapor) to the measured heat of dissociation.

The heat of dissociation of triethylaluminum dimer in the liquid phase was derived from vaporization studies as being in the range of 12.5 ± 2.0 kcal/mol of dimer, while extreme limits proposed by other investigators are in the range 8–14 kcal/mol of dimer [27, 55]. Kinetic studies on the addition reaction to alkenes are only compatible with the lower limit of this range, and both are inconsistent with the only experimental measure of this parameter, i.e., 70.7 kJ/mol (16.9 kcal/mol) of dimer, by Smith [28].

The <sup>27</sup>Al NMR signal of triethylaluminum is shifted significantly to lower field as the fraction of the monomeric form increases [58]. The <sup>27</sup>Al NMR chemical shifts of Al<sub>2</sub>Et<sub>6</sub> and AlEt<sub>3</sub> were estimated as 153 ± 2 and 265 ± 10 ppm, respectively. Using these

values, thermodynamic data were calculated for the dissociation of the  $\text{Al}_2\text{Et}_6$  dimer. Alkylaluminum alkoxides generally form trimers or higher molecular aggregates.

### 5.2.2.3 Thermodynamic Properties of Triethylaluminum

The amount of thermodynamic information available from the literature on organoaluminum compounds is scant, and what is available is often contradictory (Table 6). These variations reflect the extreme difficulties involved in handling the reactive materials, obtaining pure samples, and ensuring the complete reaction occurs in a reaction calorimeter.

**Table 6:** Enthalpy of formation of triethylaluminum.

| Enthalpy of formation |             | References |
|-----------------------|-------------|------------|
| kJ/mol                | kcal/mol    |            |
| -152.7                | -36.5       | [59]       |
| -173.2                | -41.4       | [60]       |
| -217.1                | -51.9       | [57]       |
| -235.4                | -56.5       | [61]       |
| -187.3 ± 5.1          | -44.8 ± 1.2 | [35]       |

The standard enthalpy of formation for triethylaluminum listed in PEPCODED.DAT under ingredient number 1466 (+137.2 kJ/mol = +455 cal/g = +32.8 kcal/mol) is in error [62]. Most likely, a minus sign should be added, but even then the value is outside the range of all other values reported in the literature.

The heats of combustion of triethylaluminum, diisobutylaluminum hydride, and diethylaluminum hydride were determined at an oxygen pressure of 25 atm in a combustion bomb and calculated as  $5114 \pm 9$ ,  $6299 \pm 16$ , and  $3676$  kJ/mol ( $1222.3 \pm 2.1$ ,  $1505.5 \pm 3.9$ , and  $878.7$  kcal/mol), respectively [57]. The enthalpies of formation of triethylaluminum, diisobutylaluminum hydride, and diethylaluminum hydride derived from their heats of combustion were -217.1, -402, and -307 kJ/mol (-51.9, -96.1, and -73.5 kcal/mol), respectively. The latent heats of evaporation of  $\text{Et}_3\text{Al}$ , iso- $\text{Bu}_2\text{AlH}$ , and  $\text{Et}_2\text{AlH}$  were 60.2, 35.6, and 46.9 kJ/mol (14.4, 8.5, and 11.2 kcal/mol), respectively.

Enthalpy of formation data on 450 organometallic compounds of main group I–VI metals and metalloids are summarized in [63]. The average dissociation energies of 115 types of chemical bonds formed by non-transition elements in their organic compounds were calculated from the enthalpies of formation and correlated with their position in the periodic table of elements.

The standard enthalpy of formation of liquid triethylaluminum  $\text{AlEt}_3$  was determined from the experimental enthalpy of reaction of  $\text{AlEt}_3$  with acetylacetone

in toluene [35]. The resulting enthalpy of formation of liquid  $\text{AlEt}_3$  in equilibrium at room temperature was  $-187.3 \pm 5.1 \text{ kJ/mol}$  ( $-44.8 \pm 1.2 \text{ kcal/mol}$ ) of monomer. The result was used to assess the reliability of available thermochemical data for other trialkylaluminum compounds.

In order to resolve conflicts between published heats of formation of alkylaluminum compounds and related compounds, a one-constant equation (the *displacement rule*) was derived that relates the  $\Delta H_f^\circ(\text{M}, \text{g})$  ( $\text{M}$  = monomer) of primary alkyls (other than methyl) of any element to the  $\Delta H_f^\circ(\text{g})$  of the alkane  $\text{RH}$  [64]. This rule, which permits the calculation of the  $\Delta H_f^\circ$  values of all the primary alkyls (other than methyl) of an element, including mixed alkyls and “iso”-alkyls, yields values that are practically identical to those given by the Allen bond-energy scheme. It was shown that, for many metals, the rule can be extended to include methyl compounds. Values of  $\Delta H_f^\circ(\text{G})$  and  $\Delta H_f^\circ(\text{L})$  were tabulated for a number of primary alkyls of Zn, Hg, B, Al, and Sn. For straight-chain R groups with  $\geq 2$  C atoms, the results were well represented by equations of the form  $-\Delta H_f^\circ(298 \text{ K}) = A + B(N - 2) \text{ kcal/gformula weight}$  (where  $N$  is the number of C atoms). For the gaseous monomers, the constants A and B were as follows:  $\text{R}_2\text{Zn}$ : -8.3, 9.86;  $\text{R}_2\text{Hg}$ : -17.8, 9.86;  $\text{R}_2\text{AlH}$ : 11.1, 9.86;  $\text{R}_3\text{B}$ : 36.4, 14.79;  $\text{R}_3\text{Al}$ : 27.9, 14.79, respectively. See also [65].

### 5.2.3 Chemical Properties of Triethylaluminum

Triethylaluminum and diethylaluminum autoignite spontaneously in air and react vigorously with water. These compounds must be stored in breakproof containers hermetically sealed with an inert gas pad of dry nitrogen or argon.

#### 5.2.3.1 Reactions of Triethylaluminum

The most important reaction of triethylaluminum is that with titanium tetrachloride and zinc chloride to form a catalyst that allows low-pressure polymerization of ethylene or propylene into polyethylene and polypropylene. Other reactions of triethylaluminum with ethylene lead to oligomerization, initially to 1-butene but (in the absence of catalytic trace metals) eventually to higher alkylaluminums that can be converted by hydrolysis or oxidation to  $n$ -alkanols and alkylcarboxy (fatty) acids, which have many industrial uses. Alkylaluminum compounds form complexes with non-protic Lewis base solvents such as ethers or tertiary amines.

#### Oxidation of Triethylaluminum

The amount of oxygen consumed in the first stage of the oxidation of triethylaluminum in air is only about one-third of the stoichiometrically possible amount [66]. Thus, this reaction corresponds to the oxidation of only one of the three alkyl groups in the molecule. A graph of the composition of the gases leaving the reaction chamber shows that all oxygen is consumed up to a certain point, the same point where the rate of

ethane and hydrogen evolution maximizes. Diethyl monoethoxyaluminum reacts with oxygen much more slowly.

### Ignition of Triethylaluminum

Triethylaluminum ignites spontaneously in air or in contact with LOX [17, 18, 67].

### Hydrolysis of Triethylaluminum

Because the reaction between triethylaluminum and water is so violent, this reaction has even been considered for the propulsion of underwater ramjets.

#### 5.2.3.2 Thermal Decomposition of Triethylaluminum

The pyrolysis of metal alkyls proceeds primarily as a free radical reaction. If the alkyl group has more than one carbon atom, the resulting free alkyl radical can disproportionate into an alkane and an alkene. Some metal alkyls, for example ethylsodium and diethylmagnesium, do not decompose to the free metal but to a metal hydride. The pyrolysis of triethylaluminum vapor at 523 K (250 °C) [68] gave 0.639 H<sub>2</sub>, 0.22 C<sub>2</sub>H<sub>4</sub>, 0.056 C<sub>2</sub>H<sub>6</sub>, and 0.513 C<sub>4</sub>H<sub>8</sub>. The pyrolysis of trimethylaluminum proceeded quite differently, and the overall reaction was

The kinetics of the thermal decomposition of gaseous triethylaluminum were studied in static systems over the temperature range of 435–465 K (162–192 °C), and the extent of the reaction was monitored by complete chemical analysis of the products [69, 70]. At various stages of the reaction, the following species were observed: C<sub>2</sub>H<sub>4</sub>, C<sub>2</sub>H<sub>6</sub>, 1-C<sub>4</sub>H<sub>8</sub>, 2-C<sub>4</sub>H<sub>8</sub>, H<sub>2</sub>, metallic Al, and lesser amounts of CH<sub>4</sub>, C<sub>4</sub>H<sub>10</sub>, and C<sub>6</sub>H<sub>12</sub>. The best fit to the kinetic data in terms of the disappearance of aluminum–ethyl bonds was to a first-order heterogeneous reaction with the rate expression

$$k_1 = 10^8 \cdot e^{-29000/RT}.$$

A mechanism involving concurrent molecular and free radical processes was proposed for the pyrolysis of AlEt<sub>3</sub>. There may be an equilibrium for the system

The pyrolysis of alkylaluminum compounds other than trimethylaluminum can be used for the chemical vapor deposition of thin aluminum layers on substrates that cannot withstand the higher temperatures of aluminum vacuum deposition [71, 72].

#### 5.2.3.3 Analysis of Triethylaluminum

Alkylaluminum compounds can be analyzed by gas chromatography [73]. Triethylaluminum or diethylaluminum hydride or triethylborane, liquids that are frequently used as ignition fluids for non-hypergolic bipropellant combinations or solid propellants,

can be analyzed by spectroscopic methods [74]. Diethylaluminum can be assayed by a gas volumetric method [75]. See also [76].

#### 5.2.4 Handling of Triethylaluminum

Because triethylaluminum and other trialkylaluminum compounds are pyrophoric, ignite spontaneously in air, and react vigorously with water, the handling of triethylaluminum requires special precautions and careful training of launch site operators. Because most dialkyl- and trialkylaluminum compounds, in particular triethylaluminum, are pyrophoric in air, they can be handled only under an inert gas (argon, nitrogen) [77]. Argon is preferred because it is heavier than air and it is less likely that air will intrude into the apparatus when the purge gas flow rate is too slow. Transport and storage containers should have two outlets, one for pressurization with an inert gas and the other a dip tube for withdrawal of liquid.

Additional information is available from the manufacturer's literature and chemical process safety organizations [78]. The cited reference is a CD containing 1000 papers and 20000 pages of process safety information, with presentations from the Loss Prevention Symposia, sponsored by AIChE's Safety and Health Division, from 1967 to 2003, and CCPS conference and workshops from 1987 through 2003, including papers that were delivered but not published elsewhere. This CD-ROM is fully indexed, allowing users to run searches based on author, title, subject, or keyword.

Alkylaluminum compounds with alkyl groups of  $C_4$  and below ignite immediately on exposure to air unless they are diluted with a hydrocarbon solvent to concentrations below 10–20% [1]. Even these solutions may ignite on prolonged exposure to air because of exothermic autoxidation, which occurs rapidly if the solutions are spilled [79]. For  $C_4$  and below, 10 to 20 mass-% of alkylaluminum is generally non-pyrophoric. For  $C_5$  and up, the concentration can be increased to 20–30%.

The ignition characteristics of a combustor and gas generator for a LOX/kerosene liquid rocket engine were determined experimentally through a series of combustion tests of a sub-scale engine combustor and gas generator [80]. The operation of a gas-torch ignitor based on gaseous methane and gaseous oxygen was compared with hypergolic ignition using triethylaluminum. The gas-torch ignitor performed well at igniting propellants in the sub-scale liquid rocket engine combustor and gas generator. It was noted that the ignition delay was also affected by the level of nitrogen in the combustion chamber.

A hazard ranking score (HRS) was developed for hazardous chemicals. This was a composite index based on autoignition temperature, flammable range in air, the NFPA parameter, the ionization potential parameter (for ease of detection), and TNT equivalency [81]. Chemicals were ranked on a scale from 0 (safe) to 100 (extremely hazardous). The NFPA diamond summarizes the hazard of chemicals through four characteristics: health, flammability, instability or reactivity, and special hazard. On

a scale from 0 to 100, triethylaluminum received a hazard ranking score of 57.8. For comparison, UDMH received an HRS of 42.9 and pentaborane was ranked at 64.4.

#### 5.2.4.1 Triethylaluminum Accidents

Experiments were conducted in an effort to explain an explosion in a triethylaluminum production plant in Japan in 2007. Closed-vessel tests and chemical equilibrium calculations showed that, under closed vessel conditions, the mixture of  $\text{AlEt}_3$  and water decomposes into compounds with lower molecular weights than the products of the hydrolysis of TEA at atmospheric pressure [82]. Experiments also demonstrated that large temperature and pressure increases could occur because of contact between  $\text{AlEt}_3$  and aluminum hydroxide. Since aluminum hydroxide contains water as alumina hydrates, aluminum hydroxide could have been a source of water at high temperatures and could have contributed to the mixed reaction between  $\text{AlEt}_3$  and water, resulting in the bursting of a steel pipe.

A triethylaluminum mixture prepared at 273 K (0 °C) with a 3:1 molar excess of carbon tetrachloride exploded violently soon after removal of the ice bath. Similar reactions must be expected with other halocarbons. A mixture of dimethylformamide solvent and triethylaluminum exploded when heated.

### 5.2.5 Safety Properties of Triethylaluminum

#### 5.2.5.1 Autoignition of Triethylaluminum in Air

Alkylaluminum compounds are often diluted in hydrocarbon solvents for safe storage and shipment. Results obtained with a quantitative method for measuring the self-ignition limits of alkylaluminum pyrophoric compounds in hydrocarbons at 293 K (20 °C) indicated that the pyrophoric reactivity increased in the order triethylaluminum, diethylaluminum hydride, trimethylaluminum [83].

#### 5.2.6 Toxicity of Triethylaluminum

Because triethylaluminum is so reactive with air and moisture, there is little chance that it will reach living tissue before it becomes oxidized or hydrolyzed or bursts in flames. Nevertheless, the toxicity of triethylaluminum was investigated [84]. Mice, rats, and rabbits were exposed to triethylaluminum vapors and combustion products for 30–90 min. Characteristic changes in the lungs of animals exposed to triethylaluminum were found upon histological examination. The direct action of triethylaluminum on the skin was identical to that of a burn. The changes in the lungs were a result of moderate irritation. The vapor autoignited at Hg partial pressures in air down to 0.15 ppm. The ACGIH/OSHA/NIOSH-recommended maximum tolerable concentration of alkylaluminum vapor in air is  $2\text{ mg/m}^3$  (as Al) for both PEL and 8-h TLV TWA.

### 5.2.7 Fuel Mixtures with Triethylaluminum

The most important fuel mixture with triethylaluminum is the mixture with triethylborane, which is used as a hypergolic ignition fluid in LOX rocket engines. Apparently, the mixture has better ignition properties than either of its constituents by themselves. Triethylborane helps to reduce the viscosity of the mixture. Combustion of triethylaluminum has a higher heat output. There are insufficient data on physical properties of the mixtures in the open literature.

## 5.3 Diethylaluminum Hydride

Diethylaluminum hydride,  $(C_2H_5)_2AlH$ ,  $Et_2AlH$ ; aluminum, diethylhydro-; CAS RN [871-27-2], is an important intermediate in the production of triethylaluminum by the high-pressure method.

### 5.3.1 Preparation of Diethylaluminum Hydride

Diethylaluminum hydride can be prepared by hydroalumination of ethene under pressure in the presence of triethylaluminum [85–87]. It is an important intermediate or precursor in the production of triethylaluminum.

### 5.3.2 Physical Properties of Diethylaluminum Hydride

Diethylaluminum hydride,  $(C_2H_5)_2AlH$ , CAS RN [871-27-2], has a molecular mass of 86.1 g/mol and a density of 0.7938 g/cm<sup>3</sup> at 298 K (25 °C). It freezes at 214 K (–59 °C) and boils at 322–324 K at 0.14 Pa (49–51 °C at 0.001 mm Hg). The vapor pressure of diethylaluminum hydride can be calculated from

$$\log p = 7.7273 - 2454.5/T$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin [57].

The heat of combustion of diethylaluminum hydride was determined at an oxygen pressure of 25 atm in a combustion bomb, and was calculated as 3676 kJ/mol (878.7 kcal/mol) [57]. The enthalpy of formation of diethylaluminum hydride derived from the heat of combustion was –307 kJ/mol (–73.5 kcal/mol). The latent heat of evaporation of  $Et_2AlH$  was 46.9 kJ/mol (11.2 kcal/mol) [57]. The dialkylaluminum hydrides and amides are trimeric.

### 5.3.3 Chemical Properties of Diethylaluminum Hydride

Diethylaluminum hydride is just as pyrophoric in air or in contact with LOX as triethylaluminum. It vigorously reacts with water. It reacts with ethylene to form triethylaluminum.

## 5.4 Other Alkylaluminum Compounds

### 5.4.1 Propylaluminum Compounds

Tri-*n*-propylaluminum,  $(n\text{-C}_3\text{H}_7)_3\text{Al}$ , CAS RN [102-67-0], has a molecular mass of 156.2 g/mol and a density of 0.8207 g/cm<sup>3</sup> at 298 K (25 °C). It freezes at <213 K (<60 °C) and boils at 329 K at 27 Pa (56 °C at 0.2 mm Hg).

Data for the enthalpy of formation of tripropylaluminum listed in the literature are  $-322.2 \pm 4.6$  kJ/mol and  $-282 \pm 15$  kJ/mol, i.e., showing that there is a wide scatter of data [35]. The same source gives the enthalpy of formation of tri-*n*-butylaluminum as  $-372.4 \pm 5.7$  and that of tri-*tert*-butylaluminum as  $-388.3 \pm 7.7$  kJ/mol and  $-292 \pm 30$  kJ/mol.

### 5.4.2 Butylaluminum Compounds

Triisobutylaluminum,  $(i\text{-C}_4\text{H}_9)_3\text{Al}$ , CAS RN [100-99-2], has a molecular mass of 198.3 g/mol and a density of 0.7822 g/cm<sup>3</sup> at 298 K (25 °C). It boils at 331–333 K at 0.013 Pa (58–60 °C at 0.0001 mm Hg). The decomposition of triisobutylaluminum depends on the operating conditions: in a venting reactor, the reaction proceeds in accordance with

but under pressure, the course of the reaction is

followed by decomposition of the trimethylaluminum [43]. Aluminum deposited by CVD contains varying amounts of aluminum carbide. The addition of alkenes onto alkylaluminum compounds reverses itself at temperatures above 473 K (200 °C). Secondary reactions may result in the formation of  $\text{AlH}_3$ .

The enthalpy of formation of triisobutylaluminum, CAS RN [100-99-2], also called aluminum, tris(2-methylpropyl)-, was determined by measuring its heat of combustion under standard conditions in a calorimetric bomb ( $\Delta H_{\text{comb}} = 9126 \pm 30$  kJ/mol =  $2181.2 \pm 7.1$  kcal/mol), and this value was used to calculate the enthalpy of formation ( $\Delta H_f^\circ = -292$  kJ/mol =  $-69.9$  kcal/mol) [88]. Triisobutylaluminum freezes at 273 K (0 °C) and boils at 359 K (86 °C at 10 mm Hg). The density is 0.781 g/cm<sup>3</sup> at 298 K (25 °C). The heat of vaporization of triisobutylaluminum is  $\Delta H_{\text{vap}} = 37.2$  kJ/mol = 8.9 kcal/mol.

The vapor pressure of diisobutylaluminum hydride as a function of temperature can be calculated by the equation

$$\log P = 5.8666 - 1883.3/T$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin [57].

The lower trialkylaluminum compounds exist mostly as dimers. Triisobutylaluminum, a bulkier molecule, is only 39.4% associated at 283 K (10 °C) and only 16.4% associated at 313 K (40 °C) [30]. The gaseous products of the pyrolysis of tributylaluminum at 273–475 K under static conditions were analyzed by GC/MS [89].

### 5.4.3 Diethylaluminum Azide

Diethylaluminum azide, DEAA,  $(\text{H}_3\text{CCH}_2)_2\text{AlN}_3$ , is a pyrophoric liquid with properties similar to triethylaluminum that can be prepared by three different methods. The synthesis of diethylaluminum azide was optimized and the yield was increased from a value reported in the literature [90], 54, to 75%. The purified product and its molecular structure with  $D_{3h}$  symmetry were verified by elemental analysis, IR spectroscopy, and  $^1\text{H}$  NMR. It remains a liquid down to 143 K (–130 °C) [91]. Diethylaluminum azide is a trimer with a stable six-membered ring structure under ordinary conditions. This structure is consistent with the behavior of DEAA during distillation at high temperatures up to 693 K (420 °C) at 400 Pa (3 mm Hg) – it does not decompose. The etherate with THF could not be split to liberate DEAA, but decomposed explosively. When heated to 733–840 K (460–570 °C) in vacuum, DEAA rapidly decomposed without an explosion, releasing low-molecular-weight hydrocarbons and forming a microcrystalline powder identified as aluminum nitride (AlN), with particle sizes in the nanometer range. By using a cryoscopic method, the molecular mass of DEAA was determined as 379, a very small deviation from its theoretical [92] trimer molecular mass of 381. Surprisingly, the homologue dimethylaluminum azide is not a liquid but a solid that melts at 338 K (+65 °C). It exists not only as a trimer, but also as a tetramer.

The preparation method of DEAA from sodium azide and diethylaluminum chloride was optimized in terms of reactant ratio, reaction time, and temperature, and the yield was improved from 54 to 75% compared with that reported in the literature [93]. DEAA was smoothly distilled at 373–378 K (100–108 °C) at a vacuum pressure of 267 Pa (2 mm Hg). The purified product was identified by its IR spectrum.

Based on an earlier report about DEAA synthesis, the choice of solvent for the synthesis reaction, the distillation conditions, and the main properties of DEAA were further optimized [94]. The molecular structure of DEAA was determined by means of its IR spectrum and  $^1\text{H}$  NMR. The results indicated that DEAA is a trimer with a stable six-membered ring structure. DEAA could be used as a self-ignitable pyrophoric agent. Diethylaluminum azide (DEAA) was synthesized from diethylaluminum chloride and sodium azide, and the products and conditions of DEAA pyrolysis were analyzed [95]. Diisobutylaluminum chloride can be synthesized by the reaction of triisobutylaluminum and carbon tetrachloride [96]. However, one must remember that mixing other trialkylaluminum compounds with carbon tetrachloride or chloroform has resulted in explosions. Diisobutylaluminum azide (DBAA) can be synthesized by the reaction of sodium azide and diisobutylaluminum chloride in aromatic hydrocarbon solvents,

and its etherate complex (DBAA•THF) can be synthesized by the reaction of sodium azide and diisobutylaluminum chloride in tetrahydrofuran. DBAA and DBAA•THF were characterized by their IR and  $^1\text{H}$  NMR spectra.

## 6 Alkylsilanes

Silanes without alkyl groups are discussed in the chapter “Metals of the Second and Third Row of the Periodic Table of Elements, and their Hydrides” in this volume of the *Encyclopedia of Liquid Fuels*. Here we discuss alkylsilanes in the same chapter as alkylalanes. Considering that silicon is an element that is as abundant as the sand along ocean beaches, and that silanes have a very high heat of combustion, one would assume that silanes would make a good fuel for jet engines, ramjets, and rocket engines alike. There has been no lack of attempts to do so, but difficulties with realizing this fuel economically persist. It is very energy intensive to convert silicon dioxide to silanes. In terms of *in situ* resource utilization and making rocket fuels on other planets, it is more likely that prospectors will find silicon than carbon in the form of hydrocarbons (except on Saturn’s moon Titan). All alkylsilanes are used for chemical vapor deposition of silicon carbide on microelectromechanical systems (MEMS) devices and semiconductors. The physical properties of four alkylsilanes are summarized in Table 7.

The rates of flame propagation of four alkylsilanes have been determined in a tube apparatus [99, 100]. The maximum fundamental rate of flame propagation increased in the order tetramethylsilane < trimethylsilane < diethylsilane < monoethylsilane. A precise fundamental flame velocity could not be obtained for ethylsilane because of the high rate of propagation. In a graph showing the flame velocity as a function of the fraction of stoichiometric fuel concentration, the maximum flame velocities occurred at fuel-rich ratios near 1.2. In each case, the alkylsilanes had considerably higher flame velocities than the hydrocarbons that would result if the silicon were replaced by carbon, whereas the physical properties of the alkylsilanes resemble those of the corresponding hydrocarbons. When diethylsilane was blended with *n*-pentane, no marked increase in the flame velocity of *n*-pentane occurred until the concentration of diethylsilane was greater than 20%. Comparing the flame velocities for a series of alkylsilanes with their minimum explosion temperatures, a number of trends immediately become apparent. The maximum flame velocity increases rapidly as the number of silicon-to-hydrogen bonds is increased. Similarly, the minimum explosion ignition temperature decreases markedly.

Table 7: Physical properties of alkylsilanes.

## 6.1 Methylsilanes

Methylsilanes are gases at room temperature and do not ignite spontaneously in air. The enthalpies of formation of silane and methylsilanes are summarized in Table 8. Results from theoretical calculations of enthalpies of formation for these compounds (not shown here) were close to the experimental results.

**Table 8:** Enthalpies of formation of gaseous silanes and methylsilanes.

| Compound                                         | Enthalpy of formation, experimental<br>kJ/mol | Enthalpy of formation, extrapolated from<br>the redistribution equilibrium constant |
|--------------------------------------------------|-----------------------------------------------|-------------------------------------------------------------------------------------|

Data sources: [101–103]

The temperatures required for the rapid oxidation or explosion of air/alkylsilane (methylsilane, dimethylsilane, trimethylsilane, tetramethylsilane and vinylsilane) mixtures at 1atm pressure were determined in a preheated Pyrex reaction vessel of diameter 1.5in. and length 10.5in. [104–106]. Over a fuel concentration range of 2–10%, the lowest temperatures below which explosion did not occur for the five fuels studied were: tetramethylsilane 723K = 450 °C; trimethylsilane 583K = 310 °C; dimethylsilane 493K = 220 °C; methylsilane 403K = 130 °C; and vinylsilane H<sub>2</sub>C=CH—SiH<sub>3</sub>, 363K = 90 °C. The initial rate of oxidation of a 50% mixture of trimethylsilane and air was studied by measurement of pressure and concentration changes at a temperature slightly below the explosion temperature.

### 6.1.1 Methylsilane

Methylsilane, H<sub>3</sub>CSiH<sub>3</sub>, CAS RN [992-94-9], can be prepared by reduction of methyltrichlorosilane with lithium aluminum hydride in dioxane:

The same procedure also works for the preparation of ethylsilane:

Methylsilane is a gas at room temperature and does not ignite spontaneously in air.

### 6.1.2 Dimethylsilane

Dimethylsilane,  $(\text{H}_3\text{C})_2\text{SiH}_2$ ,  $M = 60.17 \text{ g/mol}$ , CAS RN [1111-74-6], is a gas at room temperature and condenses to a liquid with a density of  $0.680 \text{ g/cm}^3$  at  $253 \text{ K}$  ( $20^\circ\text{C}$ ). It solidifies at  $123 \text{ K}$  ( $-150^\circ\text{C}$ ).

### 6.1.3 Trimethylsilane

Trimethylsilane,  $(\text{H}_3\text{C})_3\text{SiH}$ , CAS RN [993-07-7], can be prepared by reaction of a Grignard reagent with a trihalogensilane in absolute diethyl ether:

Trimethylsilane is a clear liquid that boils at  $282 \text{ K}$  ( $9^\circ\text{C}$ ), so at room temperature it is a gas. Trialkylsilane compounds are flammable but do not tend to ignite upon contact with air (in contrast to silane  $\text{SiH}_4$ ).

### 6.1.4 Tetramethylsilane

Tetramethylsilane,  $(\text{H}_3\text{C})_4\text{Si}$ ,  $M = 88.2236 \text{ g/mol}$ , CAS RN [75-76-3], is a clear liquid that boils at  $300 \text{ K}$  ( $27^\circ\text{C}$ ). It is combustible but does not ignite upon contact with air (in contrast to silane  $\text{SiH}_4$ ).

The vapor pressure of tetramethylsilane in the range  $208.93$ – $293.64 \text{ K}$  can be calculated from an Antoine equation,

$$\log(P) = 3.97703 - [1047.272/(T - 36.057)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin [107, 108]. The enthalpy of formation of tetramethylsilane vapor at  $298 \text{ K}$ ,  $\Delta H_f^\circ(\text{G})$ , is  $-286.60 \text{ kJ/mol}$ . The heat of vaporization at its normal boiling point is  $24.204 \text{ kJ/mol}$ . The Si–C bond dissociation energy is  $355.0 \text{ kJ/mol}$ .

Tetramethylsilane is flammable in air. The range of detonability of oxygen/tetramethylsilane vapor mixtures is  $1.8$ – $50 \text{ vol.-%}$  tetramethylsilane in binary mixtures [109]. For ternary mixtures, detonation still propagates with mixtures containing  $0.9\%$  tetramethylsilane,  $7.8\%$  oxygen, and  $91.2\%$  helium.

The thermal decomposition of tetramethylsilane diluted in argon was studied behind the reflected shock waves in a single pulse shock tube in the temperature range of  $1058$ – $1194 \text{ K}$  [110]. The major products formed in the decomposition were methane and ethene, whereas ethane and propylene were detected only in lower concentrations. The decomposition of tetramethylsilane seems to be initiated by Si–C bond scission to form methyl radicals  $\text{H}_3\text{C}^\bullet$  and trimethylsilyl radicals  $(\text{CH}_3)_3\text{Si}^\bullet$ .

Tetramethylsilane is a precursor for flame synthesis of silica nanoparticles. A chemical reaction mechanism was developed for the oxidation of tetramethylsilane in a lean, low-pressure ( $p \approx 30$  mbar)  $O_2/H_2/Ar$  flame using species mol fractions obtained from molecular beam mass spectrometry measurements in a matrix-supported flat flame doped with 400, 600, or 800 ppm tetramethylsilane [111].

Laminar burning velocities were measured for several different silane fuels, including tetramethylsilane, in order to evaluate their potential for vapor cloud explosions in CVD operations [112]. Laminar burning velocities were determined from constant-volume explosions in a closed spherical vessel, and the pressure rise of the initial portion of flame propagation was used to calculate the laminar burning velocity. The adiabatic flame temperature for tetramethylsilane combustion in air is 2396 K. The unstretched laminar burning velocity of tetramethylsilane in air is  $65 \pm 5$  cm/s, which is almost twice as fast as that of methane.

## 6.2 Ethylsilanes

Ethylsilanes can be prepared by hydrosilylation, the addition of silanes to ethene. Ethylsilanes can be handled in air without appreciable oxidation or hydrolysis. The compounds containing many silicon-to-hydrogen bonds, such as ethylsilane or diethylsilane, have a tendency to hydrolyze when kept in contact with water for extended periods of time.

The spontaneous ignition temperatures of a number of alkylsilanes were determined and compared with the chemical structures of these compounds, leading to a qualitative discussion of the possible influence of silicon-hydrogen bonds on the ease of oxidation, as indicated by differences in spontaneous ignition temperature [113]. Thus, with ethylsilanes, the ease of oxidation decreases in the order  $(H_5C_2)_2SiH_2 > (H_5C_2)_3SiH > (H_5C_2)_4Si$ . The same order of activity was found for the methylsilane series. Differences in spontaneous ignition temperature were less pronounced in the *n*-propyl series and even less pronounced in the *n*-butyl series and the *n*-amyl series.

### 6.2.1 Ethylsilane

Ethylsilane,  $H_5C_2SiH_3$ ,  $M = 60.1704$  g/mol, CAS RN [2814-79-1], is a gas at room temperature, condenses to a liquid with a density of  $0.639$  g/cm<sup>3</sup> at temperatures below 254 K ( $-19^\circ C$ ), and solidifies at 93 K ( $-180^\circ C$ ).

### 6.2.2 Diethylsilane

Diethylsilane,  $(H_5C_2)_2SiH_2$ ,  $M = 88.2236$  g/mol, CAS RN [542-91-6], is a liquid at room temperature. It boils at 329 K ( $56^\circ C$ ).

### 6.3 Other Alkylsilanes

Attempts to synthesize more energetic alkylsilanes as rocket fuels by replacing saturated alkyl groups with unsaturated alkenyl and/or alkynyl groups were not successful. Tetraethynylsilane is a solid that explodes on rapid heating [114]. Attempts to patent tri- and tetra-substituted ethynylsilanes wherein the substituents are higher homologs of acetylene (e.g., substituted ethynyl moieties with three to ten carbon atoms) as ramjet or rocket fuels were abandoned [115]. Isobutylsilane boils at 321.7 K (48.6 °C) and *n*-butylsilane boils at 329.5 K (56.4 °C). Vinylsilane boils at 250.3 K (−22.8 °C).

## 7 Alkylzinc Compounds

Diethylzinc, (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>Zn, CAS RN [557-20-0], was one of the first organometallic compounds. Diethylzinc ignites spontaneously in air and has been used in incendiary weapons and as an ignition fluid in rocket engines with non-hypergolic bipropellant combinations. Diethylzinc can be prepared from zinc powder and ethyl iodide. Organozinc compounds play an important role in the functioning of several enzymes. See also [116].

### 7.1 Physical Properties of Diethylzinc

Diethylzinc is a colorless liquid. The physical properties of diethylzinc are listed in Table 9. The saturated vapor pressure temperature dependence of diethylzinc is as follows [118]:

$$\log P_V = 7.996 - 2.012 \times \frac{10^3}{T}$$

where  $P_V$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin.

**Table 9:** Physical properties of diethylzinc.

| Property                                         | SI units                 | Other units  | References    |
|--------------------------------------------------|--------------------------|--------------|---------------|
| Molecular mass                                   | 123.50 g/mol             | 8.097 mol/kg |               |

| Vapor pressure at 293 K                          | 1.80 kPa                 | 13.5 mm Hg   | [118]         |
| Refractive index (n <sub>D</sub> <sup>20</sup> ) | 1.4936                   | —            | —             |

## 7.2 Diethylzinc as an Ignition Fluid in Rocket Engines

Diethylzinc was used as the ignition fluid during German rocket development tests with LOX/kerosene and GOX/kerosene in 1941–1944 in Fassburg/Germany [119].

## 7.3 Other Applications of Diethylzinc

Diethylzinc has been used as the ignition fluid in flame throwers in military weapons. The controlled autoxidation of dimethylzinc or diethylzinc is used for the deposition of thin zinc oxide layers on semiconductor sensors that are often used in flammable and toxic vapor detection devices. Pyrolysis at higher temperature is used for the deposition of metallic zinc films. In the past, not all books were printed on acid-free paper. Diethylzinc has been used for the bulk deacidification of valuable books in historical archives, thus preserving valuable cultural heritage items and extending their useful lifetimes.

## 8 Other Organometallic Compounds

It is highly unusual for toxic, volatile, organometallic compounds such as methylmercury, dimethylmercury, dimethylselenium, tetramethyltin, and trimethylantimony to occur naturally. They are typically resistant to air and moisture. The underlying formation pathways of methylmercury and dimethylmercury in the ocean are unknown. Methylmercury and dimethylmercury may accumulate in the fatty tissues of some fish.

# Ramjet Fuels

## Introduction

The *Encyclopedia of Liquid Fuels* contains eight chapters dealing with hydrocarbon fuels. This topic had to be sub-divided into several smaller chapters that were easier to arrange in alphabetical order in five subvolumes of equal size. The titles of the eight hydrocarbon chapters are “Alkanes,” “Alkenes and Alkynes,” “Aromatic Hydrocarbons,” “Cycloaliphatic Hydrocarbons,” “Hydrocarbons,” “Jet Fuels,” “Kerosenes,” and “Ramjet Fuels.”

This chapter on ramjet fuels – which are obviously fuels for air-breathing jet engines, not for rocket engines – may seem out of place in this *Encyclopedia of Rocket Propellants*, but there are so many similarities between ramjet fuel kerosenes and rocket engine fuel kerosenes that we feel justified in including ramjet fuels here. In many cases, the hydrocarbons in ramjet fuels are the same as those in rocket fuels; it is just the composition of the mixture that is different. The analytical methods used for both types of fuels are the same. The same comments also apply to jet fuels, which were originally intended to be discussed in the same chapter as ramjet fuels but ended up being covered in a chapter of their own. Quite often, jet fuels have been used as rocket fuels because they were readily available.

Ramjet fuels are receiving renewed interest as fuels in hypersonic missiles. Ramjet fuels are used in dual-mode propulsion systems. Dual-mode propulsion systems initially use rockets to get started, switch to ramjet mode once the necessary speed has been attained, ascend in ramjet mode until the air becomes too thin to support air-breathing combustion, and then switch back to rocket propulsion to achieve orbital velocity and complete the mission.

## 1 Ramjet Fuel RJ-4

Ramjet fuel RJ-4, TH Dimer, consists mostly of tetrahydrodimethyldicyclopentadiene. The composition and properties of RJ-4 are specified in MIL-P-82522C (26 Oct. 1990; formerly MIL-F-25558). The properties of pure tetrahydrodimethyldicyclopentadienes as chemical compounds are described in the chapter “Cycloaliphatic Hydrocarbons” in the *Encyclopedia of Liquid Fuels*.

With its high volumetric heating value of  $39.0 \text{ GJ/m}^3$  (140000 BTU/gal), RJ-4 has about 16% higher energy content than JP-4 or JP-5. Its flash point and low-temperature properties (freeze point and viscosity) are within safe ranges. The *endo* isomers are more viscous and higher freezing than their *exo* counterparts. Unfortunately, depending on the degree of control exerted during processing, there were notable batch-to-batch variations in the properties of this fuel (particularly in the low-temperature vis-

cosity) arising from varying proportions of the two isomers in the product. Thus, work was initiated to convert all *endo* isomers to the *exo* form by isomerization over an  $\text{AlCl}_3$  catalyst. The low-temperature viscosity was moderately improved, i.e., its viscosity at 233 K ( $-40^\circ\text{C}$ ) was reduced from 60 to 28 cSt. However, this was done at the expense of a slight drop (1.4%) in the heating value. The resulting isomerized fuel RJ-4I is a mixture of isomers of *exo*-tetrahydro(dimethylcyclopentadiene). RJ-4I offered a significantly improved viscosity and freezing point and better manufacturing reproducibility characteristics as compared to the standard military specification RJ-4. However, because of the added processing cost and the only marginal property improvements it provides, RJ-4I was never a serious candidate to replace RJ-4. Neither RJ-4 nor RJ-4I met the operational requirements of the Air Force. This fact led to the development of JP-10, which, when properly formulated, is the principal standard fuel used by both services.

RJ-4 was intended to be used in the Talos missile. The Bendix RIM-8 Talos was a long-range naval surface-to-air missile, and was among the earliest surface-to-air missiles to be used on US Navy ships (from 1957 to 1979). The Talos had a ramjet main stage and a solid rocket booster. A Navy ship would typically carry 30 of these missiles [1]. Replacing the JP-5 in some of the early Talos missiles with RJ-4 extended the range of the missiles [2, 3]. Note that some publications have mislabeled the main ingredient of RJ-4 as tetrahydromethylcyclopentadiene instead of tetrahydrodimethylcyclopentadiene.

### 1.1 Preparation, Production, and Availability of RJ-4

Tetrahydrodimethyldicyclopentadiene (RJ-4) can be prepared by hydrogenation of dimethyldicyclopentadiene followed by isomerization [4]. *Endo*-tetrahydrodimethyldicyclopentadiene isomers within the raw fuel stock can be isomerized to *exo*-isomers by treatment of the fuel stock with catalysts such as aluminum chloride, nickel, or pulverized, acid-treated firebrick [5].

The dimer of methylcyclopentadiene is first hydrogenated in a two-stage operation. In the first stage, the 8- and 9-positions of the dimer are hydrogenated in relatively mild conditions at 393 K ( $120^\circ\text{C}$ ). The dihydro derivative is relatively thermally stable and can then be hydrogenated under more severe conditions at 488 K ( $215^\circ\text{C}$ ) and 20–35 atm to complete the hydrogenation. The raw product, which contains too much *endo* conformer, must then be isomerized by heating for 1–4 h with acidic catalysts at 453–493 K ( $180$ – $220^\circ\text{C}$ ) [6].

## 1.2 Physical Properties of RJ-4

Physical properties of RJ-4 are summarized in Unit 1 of the *CPIA/M6 Air-Breathing Fuels Manual* [7]. The gross chemical formula for RJ-4 is  $C_{12}H_{20}$ . The C : H ratio is 0.60. Physical properties of RJ-4 are listed in Table 1. Physical properties of the pure main ingredient of RJ-4, tetrahydrodimethyldicyclopentadiene, are already reported in the chapter “Cycloaliphatic Hydrocarbons” in Volume 2 of the *Encyclopedia of Liquid Fuels*. Some of the physical properties in these sections are identical.

**Table 1:** Physical properties of RJ-4.

| Property                      | SI units                                       | Other units                               | References |

| Volumetric heat of combustion | 39.0 GJ/m <sup>3</sup>                         | 140000 BTU/gal                            | [8]        |

### 1.2.1 Thermodynamic Properties and Thermal Properties of RJ-4

#### 1.2.1.1 Heat Capacity of RJ-4

The heat capacity of RJ-4 as a function of temperature between 275 and 330 K can be calculated from the following equation [12]:

$$c_p = 0.1377 + 0.001022 T$$

where  $c_p$  is the heat capacity in cal g<sup>-1</sup> °C<sup>-1</sup> and  $T$  is the temperature in kelvin. The heat capacity of RJ-4I as a function of temperature between 275 and 330 K can be calculated from the following equation [12]:

$$c_p = 0.14126 + 0.0010066 T$$

where  $c_p$  is the heat capacity in cal g<sup>-1</sup> °C<sup>-1</sup> and  $T$  is the temperature in kelvin.

### 1.2.1.2 Heat of Combustion of RJ-4

The net heat of combustion of RJ-4I is  $42.433 \pm 0.009$  kJ/kg ( $10141.7 \pm 2.2$  cal/g) and the gross heat of combustion of R-4I is  $45.112 \pm 0.002$  kJ/kg ( $10781.95 \pm 0.57$  cal/g) [12]. An earlier report [10] from the same source gave an interim value for the heat of combustion of RJ-4 as  $10153.1 \pm 2.3$  cal/g and that for RJ-4I as  $10141.4 \pm 2.2$  cal/g.

### 1.2.1.3 Enthalpy of Formation of RJ-4

Based on a reported heat of combustion of  $10153.1 \pm 2.3$  cal/g =  $1773.33 \pm 0.37$  kcal/mol, the enthalpy of formation of RJ-4 was calculated as  $-160.8 \pm 1.7$  kJ/mol ( $-38.43 \pm 0.40$  kcal/mol). The corresponding data for RJ-4I are  $10141.4 \pm 2.2$  cal/g =  $1771.36 \pm 0.36$  kcal/mol and an enthalpy of formation of  $-169.1 \pm 1.7$  kJ/mol ( $-40.41 \pm 0.39$  kcal/mol).

### 1.2.1.4 Enthalpy of Evaporation of RJ-4

Correlation gas chromatography was used to measure the evaporation enthalpy of complex mixtures such as RJ-4, a high-energy-density cruise missile fuel [11]. RJ-4 consists of a complex mixture of *exo*- and *endo*-dimethyltetrahydrodicyclopentadienes. The evaporation enthalpy of RJ-4 is  $55.3 \pm 0.9$  kJ/mol. Correlation gas chromatography is applicable for obtaining the vaporization enthalpy of any complex mixture of materials that will pass through a gas chromatograph and for which vaporization enthalpies of suitable standards are available. Once the temperature dependence of each component is established, the results can be used to determine the evaporation enthalpy at any composition.

## 1.2.2 Chemical Properties of RJ-4

The gross chemical formula for RJ-4 is  $C_{12}H_{20}$ .

## 1.2.3 Safety Properties of RJ-4

### 1.2.3.1 Environmental Impact of RJ-4 Spills

RJ-4 and several other kerosenes were examined to measure the effects of potential environmental contamination resulting from these fuels on freshwater fish and aufwuchs [13]. Besides RJ-4, the materials evaluated included JP-4, JP-9, RJ-5, and methylcyclohexane.

### 1.2.3.2 Fire hazards of RJ-4

Per MIL SPEC MIL-F82522A [9], the flash point of RJ-4 per ASTM D93 must be in the range 333–352.5 K ( $60$ – $79.40$  °C =  $140$ – $175$  °F). The MSDS gives a flash point of 333 K ( $60$  °C =  $140$  °F). The autoignition temperature of RJ-4 is 602 K ( $329$  °C =  $625$  °F).

## 2 Ramjet Fuel RJ-5

The main ingredient of RJ-5 is composed of at least three major dimers of perhydrodinorbornadiene (PHDNBD), which make up more than 98% of the material. Properties of pure perhydrodinorbornadiene isomers are shown in the chapter “Cycloaliphatic Hydrocarbons.”

### 2.1 Preparation, Production, and Availability of RJ-5

RJ-5 was also known as Shelldyne<sup>®</sup>, which is a registered trademark of Shell Oil Company. Initially, Shelldyne was not hydrogenated, and dimerization resulted in a fuel with poor storage stability. Shelldyne-H<sup>®</sup> is the hydrogenated version of this fuel. Some Shelldyne-H<sup>®</sup> was and still is produced by Ashland Oil Company under license from Shell. Shelldyne-H is an “as synthesized” RJ-5 containing about 70 mass-% of the perhydrodibornadiene HNN isomer and smaller amounts of other PHDNBD isomers.

At the time of the development of RJ-5, the raw material used in its synthesis, norbornadiene, was commercially available from Shell Chemical Co. in the Netherlands as a byproduct of pesticide manufacturing. However, this Shell operation was subsequently discontinued and norbornadiene became unavailable in commercial quantities. In view of the high energy content of RJ-5, there has been a considerable effort aimed at duplicating or mimicking RJ-5 (or RJ-5-like blends) with components derived from less costly, domestically available raw materials in the US. One such fuel under development, designated RJ-7, comprises a ternary blend of perhydrogenated cyclopentadiene trimer, the dihydro derivative of the adduct of cyclopentadiene and indene, and JP-10. RJ-7 has a greater heating value than JP-10 (151000 vs 142000 BTU/gal), but its viscosity is significantly higher than that of JP-10 (>400 vs 19 cSt at 233 K = -40 °C).

RJ-5 can be made by reacting norbornadiene (which can be synthesized from acetylene and cyclopentadiene) over a rhodium-on-carbon catalyst followed by hydrogenation and isomerization to yield the product *endo,endo*-dihydrodinorbornadiene (RJ-5):

This synthesis involved the use of an expensive rhodium catalyst, multi-step processing, and had a low overall yield. It did, however, produce a fuel with a high heating value of 44.9 MJ/L (169.7 MJ/gal = 161000 BTU/gal). This fuel has an impractically

high freezing point ( $>0^{\circ}\text{C}$ ) and a high viscosity ( $>2000\text{ cSt}$  at  $233\text{ K} = -40^{\circ}\text{C}$  in the supercooled state). When in the supercooled state, it can freeze and solidify suddenly, causing fuel system shutdown. Despite this problem, its high energy content attracted a great deal of attention, and considerable work was done to develop blends based on RJ-5 that would lower the freezing point.

## 2.2 Physical Properties of RJ-5

The gross chemical formula of RJ-5 is  $\text{C}_{14}\text{H}_{18}$ . The C : H ratio is 0.78. Physical properties of RJ-5 are listed in Table 2, in *Encyclopedia of Liquid Fuels*, chapter “Cycloaliphatic Hydrocarbons,” and in reference [14].

### 2.2.1 Freezing Point of RJ-5

Shelldyne-H<sup>®</sup> is composed of at least three major dimers that make up more than 98% of the material. This mixture of hydrocarbons produces a eutectic that has a melting point considerably lower than those of the pure dimers. By using a preparative gas chromatographic technique, chemists were able to separate the three major dimers that make up Shelldyne-H.

It was of interest to see whether any combination of two or more of these dimers would not freeze above  $219\text{ K}$  ( $-54^{\circ}\text{C} = -65^{\circ}\text{F}$ ). Numbered in order of gas chromatographic elution time, the pure dimers 1, 2, and 3 in Shelldyne-H were found to freeze at approximately  $306$ ,  $278$ , and  $281\text{ K}$  ( $92$ ,  $41$ , and  $46^{\circ}\text{F}$ ), respectively. Normally, Shelldyne-H<sup>®</sup> will contain 10–20% of dimer 1, 16–22% of dimer 2, and 55–75% of dimer 3. Since the last two dimers had the lowest freezing points, a preliminary program was initiated to determine whether mixtures of only those two dimers form eutectics that meet the  $219\text{ K}$  ( $-54^{\circ}\text{C} = -65^{\circ}\text{F}$ ) (and lower) melting/freezing point requirements. With an appropriate dimer ratio, pure Shelldyne-H will remain a homogeneous fluid down to temperatures below  $219\text{ K}$  ( $-54^{\circ}\text{C} = -65^{\circ}\text{F}$ ).

RJ-5 does not exhibit a sharp freezing point but rather complex supercooling and fractional crystallization behavior. RJ-5 undergoes essentially complete crystallization at temperatures lower than  $231\text{ K}$  ( $-45^{\circ}\text{F}$ ), followed by partial melting on warming to  $250\text{ K}$  ( $-10^{\circ}\text{F}$ ), re-solidification when this temperature is held, and re-melting on warming to  $253\text{ K}$  ( $-5^{\circ}\text{F}$ ), with the last crystal disappearing at  $268\text{ K}$  ( $+23^{\circ}\text{F}$ ). Assuming that  $268\text{ K}$  ( $+23^{\circ}\text{F}$ ) is the highest temperature at which a solid phase can exist in equilibrium with the liquid phase,  $268\text{ K}$  ( $+23^{\circ}\text{F}$ ) was recommended as the threshold freezing point, a limiting value of great importance in rocketry.

**Table 2:** Properties of RJ-5 (Shelldyne-H).

| Property                                            | SI units                                         | Other units                                                 | References |

### 2.2.2 Boiling Point of RJ-5

The boiling range of RJ-5 is 533–558 K (260–285 °C = 500–545 °F).

### 2.2.3 Vapor Pressure of RJ-5

The vapor pressure of RJ-5 in the range 350–423 K can be calculated from

$$\log P = 4.817675 - 3741.925/(549.67 + t)$$

where  $P$  is the vapor pressure in psia and  $t$  is the temperature in °F [16]. For higher temperatures, the vapor pressure can be expressed in the form of an Antoine equation,

$$\log P = 4.751597 - 2496.043/(198.863 + t)$$

where  $P$  is the vapor pressure in psia and  $t$  is the temperature in °F. The vapor pressure at 366.7 K (200 °F) is 0.96 kPa (0.00952 atm = 7.2 mm Hg).

### 2.2.4 Density of RJ-5

The densities of the individual constituents of RJ-5 and RJ-5 mixtures were measured in research aimed at lowering its freezing point. Detailed data are shown in the chapter “Cycloaliphatic Hydrocarbons.” The density of RJ-5 as a function of temperature for  $0 < t < 150$  °C can be calculated from the equation

$$\rho = 1.08716 - 0.00079288t$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $t$  is the temperature in °C. The density of RJ-5 at 311 K was predicted for higher pressures; it was predicted to be 1.057 g/cm<sup>3</sup> at saturation pressure, 1.075 g/cm<sup>3</sup> at 340 atm, and 1.084 g/cm<sup>3</sup> at 680 atm.

### 2.2.5 Viscosity of RJ-5

The viscosity of RJ-5 increases by more than two orders of magnitude between 255 and 219 K (0 and –65 °F) (Figure 1). This may present a problem during the operational use of RJ-5 at high altitudes, where atmospheric temperatures are in the sub-freezing range.

An attempt was made to decrease the cold-region viscosity of RJ-5 by adding other hydrocarbons without suffering an excessive loss of volume-specific heat of combustion of the resulting fuel mixture. The hydrocarbon additives evaluated were toluene, JP-4, JP-10, methylcyclohexane, tetralin, decalin, RJ-4 (tetrahydromethylcyclopenta-

**Figure 1:** Viscosity of RJ-5 as a function of temperature. (Reproduced and modified from [15].)

diene dimer) and isobutylbenzene [15]. The diluents with the lowest viscosity in the pure state (i.e., MCH, toluene, and JP-4) had the most significant effects on the viscosity of Shellldyne-H. Since these materials also had the lowest densities, they adversely lowered the density of the mixture to the greatest extent, resulting in lower volumetric energy. Toluene blends were found to be the most effective at reducing viscosity while maintaining volumetric heating values at significantly high levels. Of the diluents tested in an earlier Shell program, methylcyclohexane had the greatest reducing effect on the viscosity of Shellldyne-H.

Liquid kinematic viscosities  $\nu$  of RJ-5 and its constituents (perhydrodinorbornadiene isomers) were measured using factory-calibrated Ubbelohde capillary viscometers [20–22]. Densities  $D$  were measured to an accuracy of 0.1% using a dilatometer about 10 mL in volume. The shear viscosity  $\eta$  was given by the product  $\nu D$  and was estimated to be accurate to about 0.5%. Viscosity and density measurements were carried out from 323 K (50 °C) down to either about 218 K (–55 °C) or a temperature just above that where the liquid crystallized. Due to supercooling, it was possible in all cases to determine  $\eta$  and  $D$  for the liquids down to temperatures well below their equilibrium melting points. Detailed data on the viscosity of perhydrodinorbornadiene isomers and their mixtures with THDCPD are shown in the chapter “Cycloaliphatic Hydrocarbons.”

Ternary blends of Shellldyne-H, methylcyclohexane, and TH-MCPD were eventually given a new name (JP-9) per specification MIL-P-87107B. The viscosities and densities of samples of four different batches of RJ-5 were measured in the temperature range 239–341 K (–30 to +155 °F) (Table 3).

A smoothed combination of viscosity data from multiple sources is tabulated in Table 4.

**Table 3:** Viscosity and density of RJ-5.

## 2.2.6 Thermal Conductivity of RJ-5

The thermal conductivity of liquid RJ-5 was estimated to be  $0.161 \text{ W m}^{-1} \text{ K}^{-1}$  at 298 K. Estimated data for the heat capacity and thermal conductivity of RJ-5 are summarized in Table 5.

**Table 5:** Heat capacity and thermal conductivity of RJ-5.

| Temperature |     | Heat capacity                     |                                       | Thermal conductivity              |                                                       |

Data source: [16]

## 2.2.7 Thermodynamic Properties of RJ-5

### 2.2.7.1 Heat Capacity of RJ-5

The heat capacity  $c_p$  of RJ-5 was listed as  $1.30 \text{ J g}^{-1} \text{ K}^{-1}$  at 298 K [18]. Another source gave a heat capacity at 298 K of  $1.28 \text{ J g}^{-1} \text{ K}^{-1}$  ( $0.306 \text{ cal g}^{-1} \text{ °C}^{-1}$ ) [16]. Heat capacity data are shown in Table 5.

### 2.2.7.2 Heat of Combustion of RJ-5

The heat of combustion of RJ-5 is 41.579 MJ/kg (17888 BTU/lb) [19]. The net heats of combustion (averages of duplicate test runs) of four different samples of RJ-5 were measured and reported as 17936, 17772, 17855, and 17811 BTU/lb (9909, 9873, 9921, and 9895 cal/g) [23].

The *exo-exo* and *endo-endo* isomers of dihydrodinorbornadiene were separated, and their physical properties were determined separately and compared to the properties of a mix of the two isomers. The heats of combustion of the pure isomers and their mixture are listed in Table 6. The heats of combustion of the two isomers are not much different.

**Table 6:** Heats of combustion of dihydrodinorbornadiene isomers and their mixture.

| Sample                  | Gross heat of combustion |       | Net heat of combustion |       |
|-------------------------|--------------------------|-------|------------------------|-------|
|                         | BTU/lb                   | cal/g | BTU/lb                 | cal/g |
| <i>endo-endo</i> Isomer | 18693                    | 10385 | 17810                  | 9894  |
| <i>exo-exo</i> Isomer   | 18778                    | 10432 | 17895                  | 9941  |
| Blend                   | 18758                    | 10421 | 17875                  | 9931  |

Note: These are averages of duplicate test runs

Data source: [23]

### 2.2.7.3 Enthalpy of Formation of RJ-5

The enthalpy of formation of RJ-5 is +30.372 kJ/mol (+7.259 cal/mol).

### 2.2.7.4 Enthalpy of Fusion of RJ-5

The heats of fusion of samples of four pure dihydrodinorbornadiene isomers were determined by integration of DSC curves. The results are listed in Table 7.

**Table 7:** Enthalpies of fusion of dihydrodinorbornadiene isomers.

| Sample                             | Melting point | Enthalpy of fusion |        |       |          |
|------------------------------------|---------------|--------------------|--------|-------|----------|
|                                    | K             | J/g                | kJ/mol | cal/g | kcal/mol |
| <i>exo-t-exo</i> Pentacyclic dimer | 336.8         | 35.06              | 8.37   | 8.38  | 2.00     |
| <i>exo-endo</i> Hexacyclic dimer   | 294.5         | 28.24              | 6.74   | 6.75  | 1.61     |
| <i>exo-exo</i> Hexacyclic dimer    | 285.5         | 63.6               | 13.3   | 15.2  | 3.19     |
| <i>endo-endo</i> Hexacyclic dimer  | 282.9         | 70.7               | 14.5   | 16.9  | 3.46     |

Data source: [23]

### 2.2.7.5 Enthalpy of Evaporation of RJ-5

The enthalpy of evaporation of RJ-5 is identical to that of perhydrodininorbornadiene, which has been calculated as 69.5 kJ/mol for the HNN isomer and 65.4 kJ/mol for the HXX isomer.

### 2.2.8 Electrical Properties of RJ-5

The dielectric constant of an *endo-exo* mixture of RJ-5 is 2.824, 2.730, 2.691, and 2.610 at 219, 273, 295, and 342 K (−65, 32, 72.5, and 156 °F) [23].

### 2.2.9 Critical Point Properties of RJ-5

The critical temperature of RJ-5 is 780 K (507 °C) and its critical pressure is 2.551 MPa (370 psia) [16]. The critical density is 0.3 g/cm<sup>3</sup> (18.73 lb/ft<sup>3</sup>). It is unclear if these numbers are measured or extrapolated values.

## 2.3 Chemical Properties of RJ-5

### 2.3.1 Composition of RJ-5

The gross formula of RJ-5 can be expressed as C<sub>14</sub>H<sub>18.375</sub>. The C:H ratio is 0.78. The hydrogen content is 14.49 mass-%. Other sources have listed the gross formula as C<sub>14</sub>H<sub>18.15</sub>. Perhydrodininorbornadiene (PHDNBD) is the main component of RJ-5 and RJ-6 missile fuels. The gross formula of dihydrodininorbornadiene is C<sub>14</sub>H<sub>18</sub>.

Chemical synthesis of RJ-5 (perhydrodininorbornadiene) gives a mixture of many isomers. Depending on the synthesis conditions applied, one of these isomers will be the predominant form. Three different types of as-synthesized RJ-5 in which the main isomeric constituents were, respectively, HNN (93%), HXX (75%), and isomer I (57%) were used to characterize its physical properties [20–22].

### 2.3.2 Specification Requirements for RJ-5

Proposed specification requirements for RJ-5 are listed in Table 8.

## 2.4 RJ-5 Mixtures

Because of the high viscosity of RJ-5, numerous solvents have been evaluated as additives to lower its viscosity and freezing point [24, 25]. Tetrahydrodicyclopentadiene (JP-10) is used as a viscosity- and melting-point-lowering diluent for RJ-5. An RJ-5/JP-10 mixture with 36–42 mass-% JP-10 is referred to as RJ-6. The ideal solution curves of Figures 3–5 in [22] can be used to estimate the melting points of RJ-5/JP-10 blends from their compositions.

**Table 8:** Proposed specification requirements for RJ-5.

| Specification limits  |              |        |        |
|-----------------------|--------------|--------|--------|
| Carbon                | 90.07 Mass-% |        |        |
| Hydrogen              | 9.87 Mass-%  |        |        |
| Water                 | < 14 ppm     |        |        |
| ASTM distillation     |              |        |        |
| Initial boiling point | 533 K        | 260 °C | 500 °F |
| 5% Distilled          | 539 K        | 266 °C | 511 °F |
| 95% Distilled         | 543 K        | 270 °C | 518 °F |
| End point             | 547 K        | 274 °C | 525 °F |
| Recovery              | 99%          | —      | —      |

Data source: [15]

## 2.5 Compatibility with Materials in RJ-5

A 7-month compatibility investigation was conducted on materials intended to be used in ramjet fuel systems with RJ-5 (Shellldyne H) in order to select materials for a full-scale fuel system simulator [26]. The candidate materials included eight metals and eight non-metallic materials. Immersion tests were conducted on all materials at both room temperature and 344 K (71 °C = 160 °F), with the post-test specimens evaluated in terms of changes in appearance, volume, weight, tensile properties, and hardness. Candidate bladder materials were subjected to hot pressurant gases from solid-propellant gas generators while in contact with fuel in a simulated fuel cell. Based upon its compatibility with Shellldyne H, Viton was selected as the primary O-ring and seal material. Although Viton becomes stiff at 219 K (−54 °C = −65 °F), it does not embrittle, and has been used successfully for gaskets.

Guidelines for the design of ramjet systems that use RJ-5 as fuel were made available. Information included physical properties of the fuel, materials compatibility, hydraulic data and thermal design data, and a description of an RJ-5 fuel system that uses collapsing bladders for positive expulsion [27].

## 2.6 Safety Properties of RJ-5

The MSDS provided by Ashland for RJ-5 (1985) lists this chemical as “norbornadiene,” with a boiling point of 516.4 K (470 °F = 243.3 °C) and a closed-cup flash point of 368 K (203 °F = 95 °C), but this name is obviously incorrect.

## 2.7 Toxicity of RJ-5

The high-density missile fuels RJ-5 and JP-9 resisted biodegradation when incubated with water/sediment suspensions collected from aquatic habitats [28]. RJ-5 and JP-9 were not toxic to the microbial communities at concentrations of 400 mg/L, but RJ-5 was toxic to *Mysidopsis bahia* in 96-hour acute tests (LC50 88 µg/L).

## 2.8 Explosive and Fire Hazards of RJ-5

The autoignition temperature of RJ-5 in air is 507 K (234 °C = 453 °F). The flash point is 377 K (104 °C = 220 °F) (McCoy 1980).

## 2.9 Applications of RJ-5

Although RJ-5 was primarily intended to be used in ramjets, it has also been tested in turbine jet engines [29]. Ignition was a problem, but combustion tests revealed good efficiency and a good temperature distribution after combustion was achieved.

# 3 Ramjet Fuel RJ-6

The RJ-6 is a blend of RJ-5 and JP-10. The nominal composition range of RJ-6 permitted by a proposed MIL SPEC dated 14 August 1978 was 58–64 mass-% perhydrodininorbornadiene (RJ-5) and 36–42 mass-% *exo*-tetrahydrodicyclopentadiene (JP-10). The data presented here are for a nominal 60% RJ-5/40% JP-10 blend [30]. The empirical formula for this mixture is  $C_{12.09}H_{17.05}$ . Fuel mixtures including the composition of RJ-6, containing 60–90% RJ-4, are described in [6]. A mixture consisting of 73% RJ-4 and 27% JP-10 has a heat of combustion of 141000 BTU/gallon, a viscosity of 31.5 cSt at 239 K (–30 °F), 14.5 cSt at 255 K (0 °F), and 3.18 cSt at 311 K (100 °F), and a flash point of 335 K (143 °F).

## 3.1 Physical Properties of RJ-6

A proposed military specification dated 14 August 1978 at one time called for a maximum melting point (i.e., equilibrium freezing point) of 219 K (–54 °C) and a maximum kinematic viscosity of 400 cSt (a shear viscosity of approximately 4 Ps) at 219 K (–54 °C) for RJ-6 fuel. The melting point and viscosity of an RJ-5/JP-10 blend depends on its composition. The melting points and viscosities of these two components, the densities of mixtures of the three highly pure RJ-5 isomers (HNN, HXX, and isomer I), and the densities of mixtures of those isomers with JP-10 were measured [20–22].

### 3.1.1 Freezing Point (Melting Point) of RJ-6

The nominal freezing point of RJ-6 is  $< 219\text{ K}$  ( $< -54^\circ\text{C} = < -65^\circ\text{F}$ ).

### 3.1.2 Boiling Range of RJ-6

RJ-6 has a boiling range of  $455\text{--}558\text{ K}$  ( $182\text{--}285^\circ\text{C} = 360\text{--}545^\circ\text{F}$ ). Another source gave a boiling range of  $455\text{--}633\text{ K}$  ( $182.2\text{--}360^\circ\text{C}$ ) (Ashland Chemical Co. MSDS 1985).

### 3.1.3 Density of RJ-6

The density of RJ-6 as a function of temperature is listed in Table 9.

**Table 9:** Density of RJ-6 as a function of temperature.

| Temperature |                  | Density                |
|-------------|------------------|------------------------|
| K           | $^\circ\text{C}$ | $\text{g}/\text{cm}^3$ |
| 278         | 5                | 1.0245                 |
| 288         | 15               | 1.0185                 |
| 298         | 25               | 1.0100                 |
| 318         | 45               | 0.9955                 |
| 338         | 65               | 0.9815                 |

Data source: [31]

### 3.1.4 Vapor Pressure of RJ-6

RJ-6 has a vapor pressure of  $0.97\text{ kPa}$  at  $298\text{ K}$  ( $0.14\text{ psia}$  at  $77^\circ\text{F}$ ). The more volatile component of the mixture, JP-10 (b.p.:  $455\text{ K}$ ; RJ-5 b.p.:  $517\text{--}547\text{ K}$ ), would be expected to be predominant in the vapor phase (JP-10:  $5.73\text{ kPa}$  at  $298\text{ K}$ , RJ-5:  $0.048\text{ kPa}$  at  $298\text{ K}$ ).

### 3.1.5 Viscosity of RJ-6

The kinematic viscosity of RJ-6 as a function of temperature is listed in Table 10.

**Table 10:** Viscosity of RJ-6 as a function of temperature.

| Temperature |                  | Kinematic viscosity    |          |
|-------------|------------------|------------------------|----------|
| K           | $^\circ\text{C}$ | $\text{mm}^2/\text{s}$ | cSt      |
| 253         | $-20$            | 41.3                   | 41.3     |
| 273         | 0                | 15.9                   | 15.9     |
| 294.2       | 21.1             | 9.15                   | 9.15     |
| 310.9       | 37.8             | $7.05^a$               | $7.05^a$ |

<sup>a</sup> By extrapolation

Data source: [31]

### 3.1.6 Thermodynamic Properties of RJ-6

#### 3.1.6.1 Heat Capacity of RJ-6

The heat capacity of RJ-6 is  $1.43 \text{ J g}^{-1} \text{ K}^{-1}$  at 298 K ( $0.341 \text{ BTU lb}_m^{-1} \text{ }^\circ\text{F}^{-1}$  at  $77^\circ\text{F}$ ). The heat capacity of RJ-6 as a function of temperature between 260 and 465 K can be expressed by the following equation [32]:

$$c_p = 0.013913 + 0.10963 \times 10^{-2} T$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ }^\circ\text{C}^{-1}$  and  $T$  is the temperature in kelvin. A similar equation describes the heat capacity of RJ-6 between 260 and 340 K:

$$c_p = 0.0852880 + 0.0008948 T$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ }^\circ\text{C}^{-1}$  and  $T$  is the temperature in kelvin [33].

#### 3.1.6.2 Enthalpy of Formation of RJ-6

The enthalpy of formation  $\Delta H_{298}^f$  of RJ-6 is  $-229.1 \text{ kJ/kg}$  ( $-5.5 \text{ kcal/100 g} = -98.5 \text{ BTU/lb}_m$ ).

#### 3.1.6.3 Heat of Combustion of RJ-6

The lower heat of combustion  $\Delta H_{\text{comb}}$  of RJ-6 is  $41.99 \text{ MJ/kg}$ . The upper heat of combustion  $\Delta H_{\text{comb}}$  of RJ-6 is  $44.070 \text{ MJ/kg}$  ( $1053.3 \text{ kcal/100 g} = 18959 \text{ BTU/lb}_m$ ). The net heat of combustion of RJ-6 is  $41.775 \text{ MJ/kg}$  ( $998.4 \text{ kcal/100 g} = 17972 \text{ BTU/lb}_m$ ) [33, 34].

## 3.2 Chemical Properties of RJ-6

The empirical gross formula of RJ-6, a mixture of different hydrocarbons, has been written as  $\text{C}_{12.09}\text{H}_{17.05}$ .

## 3.3 Safety Properties of RJ-6

The closed-cup flash point of RJ-6 is 333 K ( $140^\circ\text{F} = 60^\circ\text{C}$ ) (Ashland Chemical Co. MSDS 1985).

## 3.4 Explosive and Fire Hazards of RJ-6

The TAG flash point of RJ-6 is 338.65 K ( $65.5^\circ\text{C} = 149.9^\circ\text{F}$ ). The autoignition temperature of RJ-6 is 505 K ( $232^\circ\text{C} = 450^\circ\text{F}$ ).

Hydrocarbons are the main mode of energy storage for all modes of transportation, be it by land, sea, air, or space. The combustion of hydrocarbons in air or oxygen

releases energy, which can propel a vehicle, and discharges nitrogen, carbon dioxide, and water or only carbon dioxide/carbon monoxide and water. Hydrocarbons retrieved from fossil fuel deposits in liquid or gaseous form are processed in oil refineries to obtain hydrocarbons in a purified state suitable for burning in internal combustion engines – either reciprocating engines in automobiles or rotary turbines in air-breathing jet engines. We do not discuss the use of hydrocarbons as heating fuels or for steam generation in stationary or mobile steam power plants here because there is not much chemistry involved in those applications, and steam-powered rockets are a thing of the past.

Evaluation criteria for hydrocarbon fuels for air-breathing jet engines are quite different from those for rockets are quite different. Not every good jet engine fuel must also be a good rocket fuel. For air-breathing engines, the heat of combustion and the density are the main evaluation criteria. For rocket fuels, low-molecular-mass exhaust products are the most desirable property because this allows high exhaust velocities and specific impulses. Density is important only for the pressure-fed systems usually found in missiles and satellites. Pump-fed rocket propulsion systems can handle liquids with a wide range of densities. If density was important for all rocket fuels, liquid hydrogen would never have made it onto the list of the best rocket fuels.

# Acknowledgments

The publication of the first two sets of this *Encyclopedia of Rocket Propellants* has been made possible with the help from many individuals whose help is gratefully acknowledged. I want to thank Professor Dr. Thomas Klapötke of the Ludwig-Maximilians University of Munich, Germany, for writing the Foreword for the Encyclopedia and for reviewing several chapters of the book. I thank Dr. Karin Sora, Vice President Science, Technology, Engineering and Mathematics (STEM) of De Gruyter Publishers in Berlin, Germany, for the initiative to get this project started. The project was overseen by Dr. Bettina Noto, Senior Manager, of De Gruyter Publishers in Berlin, Germany. The tedious copyediting process was directed by Dipl.-Ing. Yvonne Schlatter at le-tex publishing services GmbH in Leipzig, Germany. My colleague Dr. Dieter Zube of Aerojet Rocketdyne in Redmond, WA, has reviewed sections of the introduction to the book. The In-Space Communications department of Aerojet Rocketdyne has provided a photo of a development rocket engine operating on LOX/liquid methane under a NASA contract in 2007, which now decorates the covers of the five volumes of *Encyclopedia of Liquid Fuels*. Numerous colleagues and organizations granted special request copyright permissions to reproduce images from their publications in my books. Many copyright permissions for reproduction of other images were obtained through Copyright Clearance Center with special privileges as an International Association of Scientific, Technical and Medical Publishers (STM) signatory member. My son Andreas Schmidt has drawn many of the illustrations and his skillful artwork is thankfully acknowledged. My wife Hildegard Schmidt has assisted in applying manuscript formatting changes using a computer word processor. Librarians at the Library of the University of Washington (UW), Seattle, WA, were of great help in granting use of the expansive collections of the UW library and in providing on-line access to data bases. Thanks go to the staff at U.S. Department of Defense, Defense Office of Prepublication and Security Review (DOPSR) in the Pentagon for reviewing and clearing the manuscript for public release.

Eckart W. Schmidt  
Bellevue, WA, USA  
July 2022

# Index

- 1,1,4,4-Tetramethyltetrazene(2) 486
- 1,1-Dimethylhydrazine 1333
- 1,1'-Azobisformamide 519
- 1,1-Di(hydroxyethyl)hydrazine 466
- 1,2,3-Triazole 1735
- 1,2,4,5-Tetrazine 2036
- 1,2,4-Triazole 1735
- 1,2,5-Oxadiazole 1850
- 1,2-Diaminoethane 116
- 1,2-Dihydrazinoethane 470
  - Physical properties 472
- 1,2-Dimethylhydrazine 1562
- 1,2-Dinitroguanidine 635
- 1,2-Ethanediammonium dinitrate 119
- 1,3,3-Trinitroazetidine 1685
- 1,3,5,7-Tetranitro-1,3,5,7-tetraazacyclooctane 4327
  - Decomposition 4349
  - Explosive properties 4369
  - Physical properties 4328
  - Thermodynamic properties 4340
- 1,3,5-Trinitro-1,3,5-triazacyclohexane
  - Decomposition 4296
  - Explosive properties 4322
  - Physical properties 4274
  - Thermodynamic properties 4285
- 1,3,5-Trinitrotriazine 2018
- 1,3,5-Triazine 2016
- 1,3-Diazidopropane 937
- 1,3-Oxazole 1997
- 1,5-Diaminotetrazole 1917
- 2,4,5-Trinitroimidazole 1708
- 2,4,6,8-Tetranitro-1,3,5,7-tetraazacubane 1698
- 2,4,6-Trinitro-2,4,6-triazaheptane 4263
- 2,4,6-Triamino-s-triazine 2020
- 2,4-Dinitrazahexane 4227
- 2,4-Dinitro-2,4-diazapentane 4226
- 2,4-Dinitroimidazole 1705
- 2,6-Diamino-3,5-dinitropyrazine-1-oxide 2010
- 2,6-Dinitro-3,5-diaminopyridine-*N*-oxide 2003
- 2-Aminoethylhydrazine 467
- 2-Azidoethanol 921
- 2-Azido-*N,N*-dimethylethylamine 156, 926
- 2-Cyanoethylhydrazine 467
- 2-Cyanoguanidine 643
